Although the *aetiology and pathogenesis* of popliteal cyst formation are still a matter of debate the present investigation has provid ed overwhelming evidence that at least in the great majority of instances they arise from the gastrocnemio semimembranosus bursa In the present study all clinically significant popliteal cysts consisted of distended bursae Concerning the reports of early authors who from dissection studies of amputated limbs or from examination of cadavers with large popliteal cysts concluded that the cysts had formed by a hernial protrusion of the syno vial membrane through gaps in the fibrous capsule it should be pointed out that many of the knees were severely affected by tuber culosis with far advanced derangement of the joint capsule (Gruber 1846 1869 Powers 1857) It may also be attributable to the vir tual absence of joint tuberculosis that other investigators and I myself have failed to de tect any popliteal cyst on palpation of a large number of cadavers whereas quite a number of cysts have been reported in the early lite rature (see Introduction)

At operation on popliteal cysts of the pre sent study *synovial membranes* were found in the upper subgastrocnemial portion of the cysts in 50% of the cases concealing the communication but not impeding the flow of synovial fluid from the joint into the cyst Once these were removed the normal slit shaped capsular opening of the g s bursa came into view These membranes pre sumably provide a plausible explanation for the numerous operative observations of seemingly non-communicating popliteal cysts which at preoperative arthrography had nevertheless filled with contrast medium from the joint (Burleson et al 1956 Hoff man 1963 Gristina & Wilson 1964 Bryan 1967 Childress 1970)

INTRAOPERATIVE MORPHOLOGY OF POPLITEAL CYSTS

PATIENTS AND METHODS

Observations made in the course of 26 operations on popliteal cysts, all performed by the author, were analysed The mean age of the patients was 44 6 years (range 19—69 years) To diagnose suspected associated knee disorders, arthrotomy was performed in five knees and arthroscopy in 10 knees One rupture of the medial semilunar cartilage, two cases of rheumatoid arthritis, one synovitis of uncertain origin, eight cases of advanced osteoarthritis and seven cases of chondromalacia of the patella or the femoral condyles were diagnosed One menisceсtomy, two synovectomies and two advancements of the tibial tuberosity had been performed in the same session as the operation on the cyst Two of the operations were for recurrent cysts

RESULTS

At operation all popliteal cysts were confined to the medial popliteal region and identified as g s bursae from their location and their anatomical relationship to the joint capsule and the above mentioned tendons, and from the site of communication between the cyst and the knee joint Only the findings at operation which differed noteworthily from those made on the bursa at dissection described above will therefore be reported

Five cysts were about the size of the normal g s bursa, 13 were about as large as a hen's egg and seven were considerably larger, one (in a rheumatoid knee) was a giant popliteal cyst In large cysts the posterior portion was flattened by the coarse popliteal fascia, forcing the cyst to extend craniolaterally towards the neurovascular structures posterior to the gastrocnemius muscle No cyst bulged towards the centre of the popliteal space *beneath* the gastrocnemius muscle Incision of the deep fascia obviously relieved the pressure in the popliteal space, as the cyst assumed a rounded shape and protruded through the fascial gap In most cases the posterior portion of the cyst was easily isolated by blunt dissection, but some cysts with a thicker wall were firmly adherent to the surrounding tissues Anteriorly all cysts firmly adhered to the tendinous portions of the muscles It was not possible to dissect the cyst wall from these tendons or the capsule In one case the cyst extended as far as the adductor magnus tendon

Fifteen cysts contained synovial fluid of low viscosity, and the remainder more viscous fluid In five cases the fluid had a gelatinous appearance Osteocartilaginous loose bodies were found in two cysts The inner surface of the cysts was covered by far thicker and coarser ridges, membranes and septa than in the normal bursa, and diverticulae were numerous

The communication was invariably located beneath the tendon of the medial head of the gastrocnemius muscle In Figure 17 the surgical anatomy is illustrated in a semischematic horizontal cross section

The capsular opening in 13 cases had the same shape and size as those found in the anatomical dissection study In five cases thin septa and synovial bands concealed the major part of the orifice and in eight cases no opening was found although saline instilled into the joint at flexion readily appeared at the site where the communication is usually located As the operation proceeded it became apparent that membranes with marginal slit shaped apertures covered the communication (Figure 18) Several membranes with openings at various sites were common When these membranes were removed the usual bursal communication slit became visible In one knee no communication was found even though a communicating g s bursa had been demonstrated at preoperative arthrography The opening was now completely obliterated by synovial bands and membranes

DISCUSSION

Although the *aetiology and pathogenesis* of popliteal cyst formation are still a matter of debate the present investigation has provided overwhelming evidence that at least in the great majority of instances they arise from the gastrocnemio semimembranosus bursa In the present study all clinically significant popliteal cysts consisted of distended bursae Concerning the reports of early authors who from dissection studies of amputated limbs or from examination of cadavers with large popliteal cysts concluded that the cysts had formed by a hernial protrusion of the synovial membrane through gaps in the fibrous capsule it should be pointed out that many of the knees were severely affected by tuberculosis with far advanced derangement of the joint capsule (Gruber 1846 1869 Powers 1887) It may also be attributable to the virtual absence of joint tuberculosis that other investigators and I myself have failed to detect any popliteal cyst on palpation of a large number of cadavers whereas quite a number of cysts have been reported in the early literature (see Introduction)

At operation on popliteal cysts of the present study *synovial membranes* were found in the upper subgastrocnemial portion of the cysts in 50% of the cases concealing the communication but not impeding the flow of synovial fluid from the joint into the cyst Once these were removed the normal slit shaped capsular opening of the g s bursa came into view These membranes presumably provide a plausible explanation for the numerous operative observations of seemingly non-communicating popliteal cysts which at preoperative arthrography had nevertheless filled with contrast medium from the joint (Burleson et al 1956 Hoffman 1963 Gristina & Wilson 1964 Bryan 1967 Childress 1970)

The apparent discrepancy between the uniform shape of the communication in the present series of operations and the wide variety of shapes and sizes of the apertures as reported by many surgeons, may be due to the great diversity that is observed in the openings in the membranes It is obvious that closure of the aperture in such membranes will hardly result in a tight seal when the concealed underlying capsular opening is left untouched

In the clinical material of the present study a *valve mechanism* was demonstrated at the site of communication in 10 of the knees preoperatively by means of a specific arthrographic technique (Lindgren & Rauschning) In these cases contrast medium from the joint cavity readily passed over to the cyst, while no passage in the opposite direction occurred when the cyst was manually compressed As membranes and synovial folds were found at operation in these cases, it is conceivable that they constitute the pathoanatomical basis of the valve mechanism

Cryosectioning of undecalcified specimens frozen *in situ* and then removed, as modified to suit the purpose of this study, allowed an examination of the true and undistorted anatomy of the ice filled joint and bursa and the relation of the bursa to the capsule and tendons As no artifacts such as may result from conventional histological procedures occurred, the sections reflected the true interrelationship of structures at each particular level The filling of the synovial cavities with coloured water was helpful in delineating the extensions of the bursa, as the synovial membrane was tinted blue No difficulties were encountered in sectioning the bone, not even the cortical bone in the metaphysis The image obtained from the rubbed surface of the block displayed natural colours, making it easy to recognise and interpret the individual structures By observing the variations of fluid filling of the different compartments of the bursa in different positions of the knee, the functional anatomy could be examined in a "frozen" state The modifications of the technique described here do not preclude the customary collection of sections on tape (Ullberg 1979) This would permit a study of the functional anatomy not only on the macroscopic but also on the microscopic level As a particular anatomical detail can be traced and its location determined throughout the specimen, a three dimensional image is obtained Cryosectioning rendered valuable and unequivocal information in this study and would certainly be applicable to similar investigations of other musculoskeletal organs As a frozen specimen can be radiographed and sectioned in identical planes, it would lend itself particularly to comparative radiographic anatomical investigations

In the knife dissection study 54 of the 58 communicating bursae were *composite bursae*, as they consisted of the bursa beneath the gastrocnemius tendon and the capsule and the bursa between the tendons of the gastrocnemius and semimembranosus muscle This bursa is called the gastrocnemio semimembranosus bursa, although bursa subgastrocnemio gastrocnemio semimembranosa would be the proper denomination

Despite the high incidence of such communications and the fairly uniform shape of the opening, this is not described in any detail or illustrated in the contemporary standard textbooks, including those of Corning, Lang & Wachsmuth, Rauber-Kopsch, Cunningham, Benninghoff Goerttler, Grant, Hafferl and Gray In the orthopaedic literature the communication is commonly depicted as a hole through which the synovial membrane protrudes (see Introduction)

In addition, the present study demonstrated *a thin area in the capsule* in all specimens immediately distal to the line at which the postero medial capsule conjoined with or had separated from the gastrocnemius tendon Apart from this particular weak portion, the capsule was thick No other preformed soft spots liable to yield to a synovial protrusion were seen, even at the level of the posterior oblique ligament (Figures 12 and 14)

The deep portion of the bursa, commonly referred to as the "neck", i e the subgastrocnemial portion, constantly forms a cavity of considerable extent in the mediolateral direction but narrow in the sagittal plane On lateral arthrograms only its narrow dimension is seen, and for this reason it may have been misinterpreted as being a narrow stalk or pedicle

During knee extension the upper rim of the capsule is firmly compressed between the condyle and the overlying tendons Especially on the cryosections of knees that had been frozen during extension, this mechanism invariably caused a hermetic *closure of the communication* The thin capsular rim admittedly resembles the cusp of a heart valve (Figures 8 and 9), but this does not imply a unidirectional valve mechanism in all communicating bursae (Taylor & Rana 1973) As the synovial fluid is emptied from the anterior to the posterior portions of the bursa (cyst) on extension of the knee, this obviously distends its wall and this would explain why patients with popliteal cysts experience most *discomfort* when the knee is extended

The attachment of the medial meniscus to the capsule is rather loose posteriorly, whereas its central portion is intimately interwoven with the capsular fibres, a finding consistent with the observations of Oretorp (1978) The loose capsular connection of the posterior horn does not prevent the semimembranosus tendon from exerting *traction on the capsule* via its capsular arm This was also confirmed by the simulated pull on this tendon in the course of the present dissection study. On the other hand, the diagonal deformation of the communication observed on application of torque stress to the knee might have been due to traction forces from the meniscus acting on the postero medial portion of the capsule

Lindgren and Willen (1977) reported progressive rarefaction and degeneration of the fibroelastic tissue between the joint cavity and the gastrocnemio-semimembranosus bursa during ageing, which eventually, for example in combination with a sudden strain, causes the communication to occur. On the other hand, the likewise constant bursa beneath the lateral head of the gastrocnemius muscle is reported to communicate with the joint far less frequently (Bardeleben & Haeckel 1901, Fick 1904, Testut & Jacob 1909, Hafferl 1969) This difference might be explained by continuous attrition due to capsular pull, since at the medial side a heavy tendon (of the semimembranosus) inserts directly into the capsule and medially the semilunar cartilage is intimately attached to the capsule, whereas the lateral side lacks a capsular tendon insertion and the lateral meniscus is mobile in relation to the capsule The increasing incidence of communication between the knee joint and the G S bursa with advancing age and the functional and morphological findings of the present investigation would seem to suggest that this communication is a condition which is acquired during life

The apparent discrepancy between the uniform shape of the communication in the present series of operations and the wide variety of shapes and sizes of the apertures as reported by many surgeons, may be due to the great diversity that is observed in the openings in the membranes It is obvious that closure of the aperture in such membranes will hardly result in a tight seal when the concealed underlying capsular opening is left untouched

In the clinical material of the present study a *valve mechanism* was demonstrated at the *site of communication in 10 of the knees preoperatively* by means of a specific arthrographic technique (Lindgren & Rauschning) In these cases contrast medium from the joint cavity readily passed over to the cyst, while no passage in the opposite direction occurred when the cyst was manually compressed As membranes and synovial folds were found at operation in these cases, it is conceivable that they constitute the pathoanatomical basis of the valve mechanism

SUMMARY

A survey of the literature on human popliteal cysts revealed a marked divergence of opinion regarding their origin Some recent publications indicate, however, that these cysts arise from the gastrocnemio semimembranosus bursa (g s bursa) Following routine excision of a popliteal cyst, recurrences and postoperative complications are common even if a closure of its communication with the joint cavity has been attempted The present investigation was therefore undertaken to study the topographical and functional anatomy of the normal g s bursa in 120 post mortem specimens and to record the surgical morphology during the course of 26 operations on popliteal cysts

In the *anatomical investigations* both conventional knife dissections and serial cryo sectioning of large, undecalcified specimens frozen in situ were performed The original technique (Ullberg 1954, 1977) which mainly concerned whole body autoradiography of experimental animals, was applied on human joints and modified to permit a detailed examination of the undistorted macroscopic anatomy of the structures in the vicinity of the bursa The optimum surgical approach to the capsular opening was sought with due regard to the popliteal sensory nerves In knees without a communication between the joint and the g s bursa fibre light transillumination invariably revealed a weak area in the joint capsule distal to its junction with the gastrocnemius tendon No other thin portions were disclosed When a communication was present, it always appeared as a transverse slit separating this thin capsular portion from the overlying tendinous origin of the gastrocnemius Rotation of the lower leg and pull on the semimembranosus tendon, simulating intravital conditions, deformed and widened the capsular opening, indicating that even during normal use of the joint tearing forces from the capsule might exert traction on the communication The increasing incidence of communication with advancing age and the morphological findings in the present studies would suggest that this condition is acquired during life

During operation all popliteal cysts were unequivocally identified as fluid-distended communicating g s bursae, but in 50% the normal bursal communication with the joint was concealed by synovial membranes The deep portion of the cyst lacked a fibrous wall of its own and only consisted of the bursal lining of the tendons and capsule, from which the cyst could not be dissected free

Based on these morphological results an improved surgical approach is *proposed* The necessity for radical excicion of all cyst tissue is questioned The thick gastrocnemius tendon lying over the communication lends itself to form a pedicle flap for closure of the opening and for reinforcement of the weak capsular portion

CONCLUSIONS

Some anatomical features established in the present studies would seem to be of special importance for the surgical technique in operations on popliteal cysts and should receive particular attention

1 All popliteal cysts in the present series were unequivocally identified as distended communicating gastrocnemio semimembranosus bursae

2 For surgical exposure a longitudinal incision following the semitendinosus tendon would provide good access to the capsular opening and involve little risk of damage to cutaneous nerves Flexion of the knee facilitates retraction of the tendons

3 The deep portion of a popliteal cyst is the natural (bursal) synovial lining of the joint capsule and the tendons It has a considerable extension in the mediolateral direction but is narrow ventrodorsally

4 This part of the cyst cannot be isolated by dissection unless a substantial amount of tendon and muscle tissue is taken along with it Not even if this is done will a pedicle (stalk neck narrow canal) form that can be ligated divided and inverted

5 As the constancy and size of the bursa would seem to reflect its functional purpose of reducing friction between the capsule and the tendons it might be questioned whether at operation on popliteal cysts all synovial lining tissue should be radically excised as is commonly advocated axiomatically by many surgeons (see Introduction)

6 The communication between the cyst and the joint cavity invariably has the shape of a transverse slit and is located beneath the tendon of the medial head of the gastrocnemius muscle roughly 3 cm distal to its origin

7 At operation all popliteal cysts were found to communicate with the joint cavity *but in 50% extraarticular synovial membranes partially or totally concealed the bursal communication with the joint*

8 The upper rim of the capsule is sharp and the adjacent portion of the capsule is thin and on the gastrocnemius tendon no rim exists that would facilitate suturing Moreover after such closure the adjacent capsule would still be thin and liable to be torn or to yield A durable closure of the communication would also seem to demand a reinforcement of this particular area but for anatomical reasons free tendon grafts are not easily fitted into the opening

9 Capsular tearing forces obviously exert pull on the capsular opening and they must be taken into account at the surgical repair

10 As the gastrocnemius tendon is thick and as it always covers the capsular opening with sufficient overlapping it lends itself to form a pedicle flap which is easily sutured to the capsule This repair appears appropriate both to eliminate the capsular tearing forces and to reinforce the thin portion of the capsule without appreciably weakening the tendon A series of operations on popliteal cysts using this capsuloplasty has given encouraging results

We have still a long way to go before the best method of treating a fracture of the shaft of the tibia can be stated with finality. I feel sure that a closed method will eventually prevail, but we need mechanical aids to improve our control of the bone fragments. It is possible time will show that an intramedullary rod, introduced through the tibial tubercle, without exposing the fracture site, will be enough to enhance alignment as an adjuvant to closed methods. Used in this simple way the intramedullary rod will not be responsible for immobilisation; it will merely control alignment and prevent slipping of the reduced fracture.

John Charnley 1961.

We regard immediate open reduction with internal fixation as the best method of avoiding further soft-tissue damage, reducing the infection rate and healing the fracture in a correct anatomical position.

Henning Höjer, Jan Gillquist and Sten-Otto Liljedahl, 1977.

1 INTRODUCTION

The treatment of fractures of the shaft of the tibia has remained a subject of vigorous debate for several decades Hardly any other important fracture has inspired such a broad spectrum of opinion as regards optimal treatment, the extreme belief in open surgery and rigid fixation promoted by the AO-group has fueled a reaction from Dehne et al (1961), Sarmiento (1967, 1970, 1974) and their followers who have demonstrated that closed treatment, only, can prevent serious complications Between these extremes a more eclectic approach has emerged Bauer et al (1962) have shown that the incidence of deep infection and poor results are directly correlated to the cause of the fracture They proposed that the extent of soft tissue rather than bone injury should guide the choice of treatment, open surgery and internal fixation would be well tolerated in low energy fractures but quite hazardous in high energy fractures This hypothesis was confirmed by Edwards (1965) in a controlled prospective series of 161 displaced fractures with but one case of deep infection

The fact that deep infection in fractures of the tibia can be virtually avoided does not mean that treatment routines cannot be improved and simplified Edwards usually kept his fractures in a full leg-length plaster without weight-bearing until the fracture healed in open transverse fractures this treatment could last a year or more. By contrast Dehne et al (1961), Brown and Urban (1969) and Sarmiento (1967, 1970, 1974) have shown that the tibial fracture tolerates early weight-bearing but they seem to have accepted rather serious shortening and malalignment

The basis for the present investigation was to combine the principles of Edwards and Sarmiento The fractures were thus subjected to active primary treatment with open surgery and internal fixation in displaced longitudinal fractures and closed intramedullary nailing of displaced transverse fractures and they were then allowed early weight bearing with free knee motion in a below-the-knee cast Already from the start the investigation was planned to permit a close comparison not only with Edwards s series but also with Olerud and Karlström s (1972a) review of tibial fractures treated by the AO compression plate In order to simplify this comparison the definitions and terminology used by Edwards (1965) and/or Olerud and Karlström (1972a) have been used

We have still a long way to go before the best method of treating a fracture of the shaft of the tibia can be stated with finality. I feel sure that a closed method will eventually prevail, but we need mechanical aids to improve our control of the bone fragments. It is possible time will show that an intramedullary rod, introduced through the tibial tubercle, without exposing the fracture site, will be enough to enhance alignment as an adjuvant to closed methods. Used in this simple way the intramedullary rod will not be responsible for immobilisation; it will merely control alignment and prevent slipping of the reduced fracture.

John Charnley 1961.

We regard immediate open reduction with internal fixation as the best method of avoiding further soft-tissue damage, reducing the infection rate and healing the fracture in a correct anatomical position.

Henning Höjer, Jan Gillquist and Sten-Otto Liljedahl, 1977.

After exclusion of the above patients, the base material of the investigation comprised 105 patients. Two of these had bilateral fractures and three sustained re-fracture after the initial fracture had healed. In all three the re-fracture was caused by adequate trauma, in two of these the fracture occurred distant to the initial fracture. Therefore these three re-fractures were regarded as fresh fractures. The base material thus comprised 110 fractures of the tibia (Figure 1)

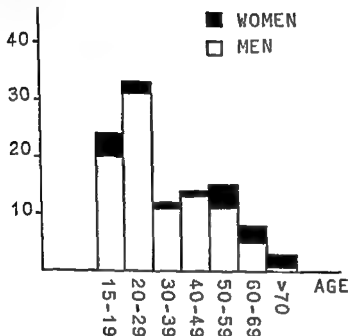

Fig 1
Age and sex distribution

Classification of the fractures (Table II)

The fractures were classified according to Edwards (1965) with but minor modifications

(1) Longitudinal vs transverse fractures. Longitudinal fractures were defined as such fractures in which the fracture line formed an angle of less than 45° with the long axis of the diaphysis. All other fractures were classified as transverse. An additional classification was introduced by distinction between simple transverse fractures with an angle close to 90° and short oblique fractures with an angle less than 90°

II. MATERIAL

This prospective investigation was started August 1, 1973 and ended June 30, 1976 The source material comprised all patients 15 years and older with a fracture of the tibia between the tibial tuberosity and 3 cm proximal to the ankle joint in whom primary treatment was started at the Department of Orthopaedics in Lund during the period of investigation and who did not receive secondary treatment elsewhere The following groups were excluded from the source material

(1) 17 patients who received primary treatment elsewhere,
(2) 11 patients who received secondary treatment elsewhere
(3) 10 patients with 11 fractures who had other injury or disease which prevented early mobilisation with weight-bearing (Table I)
(4) 3 patients who were never subjected to early weight-bearing because the surgeons in charge had misunderstood the agreed treatment schedule
(5) 3 patients with 4 fractures in which local skin- or other soft tissue problems were thought to prevent the treatment schedule One of these patients had such extreme obesity that the PTB-plaster was judged not to give sufficient stability to her rather proximal fracture One patient was an 87-year old man with such fragile skin that it was deemed unwise to apply a non-padded plaster early One patient w th b lateral tibial fractures had a crush injury of the left popliteal artery and very slow healing of the soft tissues

Table I
Fractures not subjected to early weight-bearing

Total	15	14	1	2	32

Table V

Fracture level

Proximal metaphysis	1
Diaphysis	96
Distal metaphysis	13
Total	110

(2) Displaced fractures. Fractures with minimal displacement were classified as non-displaced. Contrary to Edwards (1965) no attempt was made to sub-classify the displaced fractures; before X-ray examination all grossly displaced fractures were reduced and in six fractures traction was applied to the calcaneus. In the displaced fractures the fibula was not fractured in two longitudinal fractures, six closed transverse fractures and six open transverse fractures.

(3) Comminution (Table III). Fractures with an intermediary fragment larger than half the diameter of the diaphysis were classified as comminuted. Comminuted fractures with additional intermediary fragments were classified as grossly comminuted. When the diaphysis had fractured at two separate levels the fracture was classified as a double fracture.

(4) Closed vs open fractures. The size of the wound is shown in Table IV. In all the open longitudinal fractures the wounds were obviously caused by simple piercing of the skin from within.

(5) Fracture level (Table V). Edwards (1965) had recognized three fracture levels, proximal midshaft and distal. As it now seems well established that the healing conditions of truly diaphyseal fractures is the same regardless of level (Ellis 1958b, Nicoll 1964, Edwards 1965, Hoaglund and States 1967) it seemed more relevant to distinguish between diaphyseal and metaphyseal fractures.

Cause of the fractures (Table VI)

Traffic injury accounted for 40 % of the fractures; half of those occurred in patients riding mopeds or motor cycles. All sport fractures were soccer injuries; the lack of ski injuries is explained by the almost total absence of snow in southern Sweden during the investigation period. As regards the fractures caused by a fall, a height of 3 metres distinguished between low and high energy fractures.

Associated injury (Table VII)

Eleven fractures occurred in patients with multiple injuries. Nine of these were victims of traffic accidents, one fell from a height of 4 metres and one was involved in the collapse of a building scaffold.

Foot fracture	2
Spleen rupture	1
Brachial plexus injury	1
Total	19

These 19 injuries occurred in 11 patients

The aim of this investigation was (1) to provide primary definitive treatment as soon as possible, (2) to institute early weight-bearing in a PTB-plaster and (3) to do a follow-up not less than 6 months after the fracture

Primary treatment (Table IX)

All treatment before the application of the PTB-plaster was defined as primary treatment. Operations were planned to be performed as early as possible this meant that the operations were carried out by the surgeon on duty and therefore the number of surgeons involved at this stage was quite large, some 15. In 60 fractures the operation was performed within 24 hours, usually less than 12 hours, and in 10 fractures the operation was delayed 24 hours or more (Table VIII) The reason for this delay was concom tan injury or disease in six fractures (two head injuries, one ruptured spleen, one vertebral fracture, one intoxication, one poor skin), unacceptable init al reduction in two fractures, delays in transportat on from site of injury to the hospital in one fracture, and unknown reasons in one fracture

Table VIII
Hours between injury and definitive operative treatment

	1-6	7-12	13-24	24
Longitudinal fractures	5	8	8	3
Transverse closed fractures	7	13	1	5
Transverse open fractures	9	6	3	2
Total	21	27	12	10

In accordance with Edwards (1965) the cause of the fractures and thus the extent of skin damage decided the cho ce of primary treatment. A distinction was therefore made between longitud nal and transverse fractures

(1) Long tudinal fractures Open reduction and osteosynthesis was carried out whenever d splacement was deemed more than acceptable One, usually two or occasionally more screws were chosen rather than encircling w res wh ch provide less stab lity (Lindahl 1964) and may cause osteonecrosis (Norberg 1977) In 18 of 29 displaced fractures osteosynthesis with screw(s) was thus performed In one fracture an encircling w re was used because the fixation with screws did not succeed In five fractures closed reduction and

Table IX.

Primary treatment in tibial fractures

Type of fracture	Plaster only	Closed reduction	Rush-pin	Screw(s)	Encircling wire	Transfixation	Total
Displaced longitudinal closed	3	2	4	14	1		24
Displaced longitudinal open			1	4			5
Displaced transverse closed	4	6	25			2	37
Displaced transverse open	4	4	18	1			27
Non-displaced transverse closed	16						16
Non-displaced longitudinal closed	1						1
Total	28	12	48	19	1	2	110

Plaster was used in all cases and all fractures subjected to osteosynthesis or transfixation were reduced

osteosynthesis with a Rush-pin was preferred because of either marked swelling or osteopenia In the remaining five fractures an acceptable position was obtained without need for an open operation In the five open fractures the wound was closed with primary suture after excision of the wound margins

(2) Transverse fractures: Non-displaced fractures were treated with a long-leg cast only Displaced fractures which could be stably reduced by closed methods, likewise had a long-leg cast only If stable reduction could not be obtained, blind nailing with a Rush-pin was performed In comminuted fractures where the Rush-pin did not give sufficient stability, transfixation in plaster was preferred The Rush-pin was introduced from behind the tibial tuberosity after length-wise splitting of the patellar ligament, so as to cause as little irritation as possible from the unpadded PTB-cast The Rush-pin was chosen because it had been used successfully by Edwards (1965) and had been used for a long time in this department Three-point fixation (Rush 1955) was not aimed at, the only purpose of the pin was to prevent shortening of the fracture by sliding of the fragments In all 27 open transverse fractures the wounds were sutured primarily with a relaxing incision in only one fracture In 18 fractures the displacement was reduced to a stable position without use of osteosynthesis In 43 fractures fixation was obtained with a Rush-pin One open, short oblique fracture in the distal metaphysis was stabilized with a screw Transfixation was used in two comminuted fractures

(3) Antibiotic treatment All open fractures received antibiotics immediately on admission (Bowers et al. 1973, Patzakis et al, 1974, Gustilo and Anderson 1976, Lidgren and Sandegard 1977). As a principle fractures with small wounds were treated with penicillin and fractures with large wounds with a combination of penicillin and ampicillin In cases where there was judged to be a risk of infection with Staphylococcus aureus resistent to penicillin, the latter was substituted by cloxacillin In order to simplify this schedule all open fractures were treated with cephaloth n/cephalexin during the last six months of the investigat on

(4) Primary plaster f xation All fractures were initially stab lized with a long-leg plaster and the patients were mobilized with crutches without weight-bearing as soon as possible, usually within the first couple of days

(5) Additional primary treatment (Table X) 19 fractures required a total of eight cast removals for re-reduction under anaesthesia and 14 wedgings In one of the re-reductions the Rush-p n was partly extracted and re-inserted in a better position All wedgings were made on the long-leg cast If the fracture angulated after the long-leg

cast had been changed to a PTB-cast, a new PTB-cast was applied as recommended by Sarmiento (1974), no attempts were made to wedge the PTB-cast

In one fracture a fasciotomy was performed because of threatening compartment syndrome, after a few days a split skin graft was applied

Table X
Additional primary treatment

Re-reduction	8
Wedging	14
Fasciotomy	1
Secondary skin closure	1
Total	24

Early weight-bearing

After 2-3 weeks the long-leg plaster was removed and a PTB-cast (Sarmiento 1967) was applied if wound healing and swelling permitted (Table XII) The patients were encouraged to bear full weight in the PTB-cast as soon as it was dry and most of the patients could do this without discomfort The patients returned for X-ray control three weeks later and if they were still comfortable the original PTB-cast was retained for another six weeks At twelve weeks the plaster was removed and the fracture was examined clinically for stability and by X-ray for evidence of callus formation The decision as to whether further plaster fixation could be dispensed with was based on these examinations and on the nature of the fracture In the majority no further plaster was deemed necessary and in a few cases the plaster was removed before 12 weeks, for example in non-displaced fractures and in some where already the six-week X-ray examination showed evidence of callus formation The general schedule shown here was followed in 80% of the fractures in as much as they required only two PTB-casts (Table XI)

Table XI

Non-displaced	2	6	6	3					15 ± 2	17
Total	2	11	30	39	13	6	5	4		

Secondary treatment (Table XIII)

Because of delayed healing six fractures were treated with fibulotomy, reaming of the medullary cavity and Kuntscher-nailing (Christensen 1973) and three fractures were treated with subcortical cancellous bone-grafting (Phemister 1947, Charnley 1961) One of the graft procedures was performed after it had been found that a planned Kuntscher-nailing could not be carried through The Kuntscher-nailed fractures were allowed full weight-bearing without plaster immediately after the operation The graft operated fractures were stabilized in a PTB-cast with full weight-bearing for three months in two cases and 6 5 months in one case

Table XIII
Secondary treatment for delayed union

Kuntscher-nailing	6
Bone grafts	3
Total	9

In planning the treatment of the series of fractures described here it was decided that any secondary operation should be performed as early as possible in order to avoid unnecessary delays However, no definite time limit was set for these interventions Some of these secondary operations were performed rather late (Table XIV) because some fractures, believed to be stable, later developed pain on weight-bearing the indication for the secondary operation was pain in the fracture region and/or radiographic evidence of threatening pseudarthrosis

Table XIV
Weeks between initial injury and secondary treatment for delayed union

Type of fracture	20-29	30-39	40-49	50-59	Total
Transverse displaced closed	2	1	1	1	5
Transverse displaced open	1	1	1	1	4
Total	3	2	2	2	9

Healing times

Healing was judged to have occurred when the fracture was clinically stable and did not elicit pain on palpation or manual stress, the final plaster was thus often removed before radiographic evidence of complete healing was observed However, osteosynthesis with screws in longitudinal fractures often is quite stable and hence it was

difficult to evaluate the degree of healing in such cases clinically and by X-ray because visible callus formation was minimal In these fractures, therefore, plaster fixation was usually carried through the full twelve weeks The healing times were analyzed with graphic probit analysis (Edwards and Nilsson 1965) The healing time for fractures subjected to secondary Kuntscher-nailing could not be determ ned because these fractures were stabilized at operation These fractures were not included in the analysis of healing times

Delayed union was defined as healing time longer than 20 weeks (Nicoll 1964)

Removal of osteosynthesis material

As the patients recovered from the fracture episode, the proximal end of the Rush-pin usually caused some pain during activities like running, crouching and kneeling In most cases the pin was therefore removed after about one year, it was left in eight patients who were relatively old and inactive and did not experience any discomfort The screws were removed in only two cases and then because of aching pain in the fracture region

Follow-up

The patients were re-examined between 6 months and 3 1/2 years after the initial injury In the base material 106 out of the 110 fractures were re-examined i e 96 % Two patients with non-d splaced transverse fractures had moved far away from th s region, one patient with a comminuted transverse fracture which had healed without complications refused to appear for re-examination and one patient with a displaced longitudinal fracture had d ed from reasons unrelated to the fracture episode

The 18 fractures which for various reasons had been excluded from the source material (Groups 3-5, page 8) were subjected to re-examination However, one of these patients, a mentally retarded man, was not exam ned because he had been moved to a remote long-term care unit

The parameters examined at the re-examination (Table XV) were chosen from Edwards (1965) and Olerud and Karlström (1972a) to permit comparison w th their series In the f nal classif cation of the results observed at re-exam nation sports act v t es were disregarded most patients had never partic pated in sport activities Furthermore shortening, angulation or malrotation were disregarded unless they were symptomatic in terms of the other amined In agreement with Olerud and Karlström (1972b) those fractur as excellent with symptoms only in Group 1,

good those with one or more symptoms in Group II, acceptable those with one symptom in Group III but without any untoward subjective problems, and poor those with symptom(s) in Group III with poor function

Re-examination of the radiographic material

The radiographic material was re-examined with regard to malalignment. Displaced fractures were re-examined to ascertain whether the osteosynthesis had diminished the initial shortening. As regards angulation the true angle was determined according to Norman (1965) (see Fig. 2). For those fractures where the final angulation was more than 5° the X-ray material before and after weight-bearing in the PTB-cast was examined to evaluate whether the angulation was due to early weight-bearing.

Statistical methods

For calculation of statistical significance the Z-test, chi-square test, Fischer's exact test, Student's t-test and F-test were used.

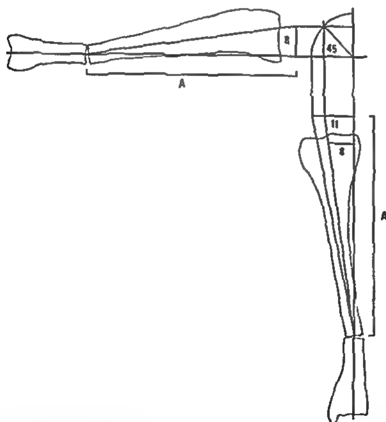

Fig. 2. Determination of the true fracture angle according to Norman (1965).
A fracture with 8° of angulation in the frontal and lateral projections. The true angle is 11° directed 45° anteromedially.

Table XV

Definition of parameters at the follow-up examination

	I	II	III
Subjective symptoms			
1 Work capacity	Unchanged	Difficulty in doing heavy work	Seated work only
2 Sports activity	Unchanged	Finished with some sport because of injury	Finished with all sports because of injury
3 Difficulty in walking	None	Slight limp after severe exercise	Constant limp
4 Pain at fracture area	None or neglibile	Moderate symptoms	Severe symptoms pain at rest
5 *Ankle joint symptoms*	*None or neglibile*	*Moderate symptoms*	*Severe symptoms*
6 Knee joint symptoms	None or neglibile	Moderate symptoms	Severe symptoms
Objective signs			
7 Knee motion	Normal	0-110°	Lack of full extension, flexion to less than 90°
8 Ankle motion	Less than 10° loss of dorsi-flexion, less than 20° loss of *plantar flexion*	Dorsiflexion over 90° less than 30° loss of plantar *flexion*	Dorsiflexion less than 90° more than 30° loss of plantar flexion
9 Foot motion	Less than 25% decrease of pro- and supination	Moderately decreased	Severely decreased
10 Foot contracture	None	Moderate	Severe cavus deformity
11 Calf atrophy	Less than 1 cm	1-2 cm	More than 2 cm
12 Malleolar swelling	Less than 1 cm	1-2 cm	More than 2 cm
13 Shortening	Less than 1 cm	1-2 cm	More than 2 cm
14 Angulation deformity	5° or less	6-10°	More than 10°
15 Rotational deformity	10° or less	11-20°	More than 20°

Complications (Table XVI)

(1) Wound infection was defined as a wound with clinical evidence of infection, thus disregarding the results of bacterial culture Deep infection was not observed in this series In six fractures a superficial wound infection was observed, none of these required more than antibiotics In two of these the infection occurred in the initial wound and in four in the operative wound (in one after open reduction of a longitudinal fracture, in one after extraction of the Rush-pin, in one after a graft operation, and in one after Kuntscher-nailing)

(2) Skin necrosis Insignificant necrosis of the wound margins was not recognized as necrosis In six fractures superficial necrosis of the skin was observed, none required skin transplantation One of these occurred over the fracture as a result of the initial trauma and in five because of pressure from the plaster Three of these occurred in the long-leg cast with two appearing at the heel and in one because of pressure after wedging Two skin necroses occurred in the PTB-cast, in one probably because of an attempt to correct an angulation during application of the PTB-cast and in the other because of pressure over the fibular head, this case also developed a partial peroneal palsy The largest necrosis caused by the PTB-plaster is shown in Fig 10

(3) Peroneal palsy One patient developed a partial peroneal palsy which had recovered completely at follow-up This patient had a long period of lowered consciousness due to a hypercalcemic crisis following an overdose of dihydrotachysterol and calcium-therapy for phenytoin induced osteopenia the absence of an adequate alarm response probably contributed to prolonged hyperpressure with peroneal injury and skin necrosis At the follow-up she also had a cavus deformity of the foot

(4) Thrombo-embolism Clinical evidence of venous thrombosis, verified by phlebography occurred in four patients in one of these the thrombosis involved the uninjured leg Two of these four patients had pulmonary embolism and an additional two patients had pulmonary embolism without previous certain diagnosis of thrombosis One of the patients with thrombosis was subjected to ligation of the inferior vena cava, thrombectomy and institution of an arterial venous shunt In one of the patients with pulmonary embolism the diagnosis was made on the basis of his verbal account during the re-examination he never sought medical advice during his thrombo-embolic episode

Table XVI

Complications in tibial shaft fractures

	Superficial wound infection	Skin necrosis due to		Peroneal palsy	Thrombosis	Embolism	Delayed union	Loose screws	Total
		Initial contusion	Pressure from the plaster						
Displaced longitudinal closed	1		1	1		2		3	8
Displaced longitudinal open		1			1				2

Displaced transverse open	1		3				7		11
Non-displaced transverse closed						2			2
Total	6	1	5	1	2	4	13	3	35

(5) Delayed union, i e healing time longer than 20 weeks, was observed in seven open and six closed transverse fractures Delayed union was not observed in longitudinal fractures among whom the longest healing time was 18 weeks

(6) Loosening of screws In three longitudinal fractures the screws loosened and the fractures re-displaced somewhat, but never to the full preoperative position The fracture with maximal displacement is shown in Fig 11

Hospitalization periods (Table XVII)

The mean hospitalization time was 13 days for transverse closed fractures and 14 days for longitudinal and transverse open fractures including hospitalization for secondary procedures However, a few patients were hospitalized for a very long time because of concomitant injury or disease, for example two patients with head injury, two pelvic fractures, one severe asthma, one severe open fracture of the elbow, one vertebral fracture, one femoral fracture, two scapular fractures of which one had a plexus injury, one alcoholism one with a hypercalcemic crisis If these patients are excluded the mean hospitalization was 7 days for longitudinal fractures and 11 days for transverse fractures It is thus better to show the median values half of the patients stayed in hospital six days for longitudinal and closed transverse fractures and seven days for open transverse fractures

Table XVII

Days of hospitalization including secondary treatment

Type of fracture	A		B

Non-displaced	1 9	2 5

Disability periods (Fig 3)

The cumulative disability period was determined for those patients who were eligible to sick-pay. Excluded from these calculations were thus students, pensioners and one woman who was pregnant After six months 2/5 of the patients with displaced longitudinal and closed transverse fractures and 1/3 of open transverse fractures had returned to their occupations. After twelve months these figures were 9/10 and 4/5 respectively. Two patients could not return to their previous occupations, one 58-year old man will probably have a disability pension and a 19-year old man was being retrained. A 68-year old man was working only half-time in his previous occupation.

Fig. 3. Disability following tibial shaft fracture.
The figure shows fraction returned to work.

Results at follow-up (Tables XIX-XXI)

The final result could not be evaluated in one patient with a non-displaced longitudinal fracture because he had previously had a double fracture and the final result was due to his initial fracture

(1) Working capacity All but two patients could return to their previous jobs However, as a result of the tibial fracture six patients had some problems when engaged in heavy work

(2) Sports activities Two patients had discontinued sport activities because of the fracture, one had continuous pain in the fracture region and one had limited function because of shortening, muscle atrophy and poor ankle motion An additional four patients had diminished their sports activities Two of them d d sprinting for exercise but did not play as much soccer as they had previously done, one had already previously had a tibial fracture through soccer and did not want to subject himself to the risk of having a third fracture, and one patient with a double fracture after he had been hit by a car had some problems which did not allow full sports activity

(3) Walking capacity Two patients had a continuous limp, i e those who had been unable to return to their previous occupations

(4) Pain Two patients had rest-pain in the fracture reg on One of those had a longitudinal fracture the rest-pain was not aggravated by weight-bearing, he had full working and walking capacity and examination did not reveal the cause One patient had very poor function after a severely comminuted distal fracture of the t b a

(5) Ankle and foot motion Four patients had objective and/or subjective symptoms of poor ankle and foot motion Two patients had severe complaints One of those had a severely displaced open distal fracture with severe soft tissue injury after he had been caught in a machine, he had only slightly decreased ankle motion The other patient had a severely comminuted fracture in a traffic accident, he had contracture of the foot as described by Karlström et al (1975) with m nimal ankle and foot motion One patient had been bone-grafted and treated in plaster for altogether 19 months, he had severely limited ankle and foot motion with contracture of the flexor hallucis longus but he had no subjective complaints, possibly because of limited activities The fourth patient had a contracted foot following a longitud nal fracture but had no subjective complaints, also in this case probably because of decreased activity, the patient was 64-years old and was in very poor general condition

Table XVIII

Fracture healing times, this series (months)

Type of fracture	50 % of the group	95 % of the group
Displaced longitudinal	2.8	4.3
Displaced transverse closed	3 1	4.8

Total	97	7	1	99	4	2	94	9	2	93	10	2	95	8	2	104	1	

(11) <u>Angulation.</u> [redacted] fractures had no angulation, the fracture angle was 5° or less. 22 fractures had an angulation of 6–10° and seven of more than 10°. In 16 of these 29 cases the fracture angle had increased by $5.9 \pm 1.3^{\circ}$ during weight-bearing, i e. during the period between the X-ray examination immediately after the first PTB-cast had been applied and the final examination The largest angulation was 31°, it had increased 20° during weight-bearing This patient was 60-years old and refused to have the angle corrected The second largest angulation was 15°, shown in Fig. 12. – In five fractures the angle was open anteriorly, in eight medially (varus) and in 11 antero-medially In three fractures the angle was open posteriorly, in one posterior-medially and in one posterior-laterally. – Five of the fractures with angulation of more than 5° were longitudinal (one with encircling wire, two Rush-pins, one screwed, and one without osteosynthesis and with a non-fractured fibula), and 24 were transverse (19 with Rush-pins and five without osteosynthesis of which three had a non-fractured fibula).

(12) <u>Rotational deformity</u> Malrotation was observed in four fractures but did not seem to cause any complaints The largest malrotation was 30° in a 73-year old man and the next largest 20° in a 70-year old woman, permanently confined to a long-term institution

(13) <u>Over-all classifications of the final results (Table XXI)</u> The over-all results in this series of 105 fractures evaluated were 67 % excellent, 24 % good, 6 % acceptable and 3 % poor However, as expected, the over-all results in the non-displaced fractures were uniformly excellent The results in the 91 displaced fractures were 57 excellent 24 good, 7 acceptable and 3 poor – The results at re-examination of the 17 fractures which had not been subjected to early weight-bearing are shown in the list of coded data The functional result in this group was sometimes impossible to evaluate because of other disease and injury. Of the three fractures which by "mistake" were not subjected to early weight-bearing two would had been classified as excellent and one as good

(6) Knee motion All patients had normal knee motion Only one had complaints from the knee, probably unrelated to the fracture This case was a 60-year old man with a longitudinal fracture who after the fracture had healed was operated on for a meniscus lesion and who had clinical evidence of femoro-patellar arthrosis at the re-examination

(7) Additional complaints Five patients complained of pain or discomfort elicited from the scar above the tibial tuberosity at kneeling None of these patients felt that these sensations constituted any major problem One patient had a muscle hernia which felt uncomfortable after excessive walking, he refused surgery of the hernia

(8) Muscle atrophy The circumference of the fractured leg was compared with that of the normal leg On the basis of this comparison 89 legs had a muscle atrophy of less than 1 cm, 15 between 1 and 2 cm and only one more than 2 cm This latter case was an open double fracture with a large soft tissue injury but without any subjective complaints

(9) Swelling Swelling was evaluated by comparison of the c rcumference just proximal to the ankle joint of both legs 90 legs had swelling of less than 1 cm, 11 between 1 and 2 cm and four more than 2 cm The largest swelling was 4 cm in a patient who had had a longitudinal fracture This patient had marked varicosit es b laterally and had been operated on for this reason on the non-fractured s de Of the 11 patients with moderate swelling one had had thrombosis of the contralateral leg None of the other three patients with phlebographic evidence of thrombosis had any swelling on re-examination

(10) Shorten ng 88 legs had shorten ng of less than 1 cm, 14 had shortening of 1-2 cm and three had shortening of more than 2 cm Of the 14 legs with moderate shortening, six occurred after long tudinal or short oblique fractures (four w thout osteosynthesis and two with Rush-pins), eight occurred in transverse fractures which had either delayed healing, were comminuted or double (six of these had a Rush-pin, one was transfixed and one was treated without osteosynthesis) In two of these cases the f bula was not fractured but they had healed in varus and the leg length was measured between the medial joint line of the knee and the t p of the med al malleolus Of the three legs with shortening of more than 2 cm, two had double fractures with 2 5 cm shortening and one with 3 5 cm of shortening had a severe comm nuted fracture wh ch healed only after grafting the primary treatment in all these three fractures was by Rush-pinning

(11) Angulation [redacted] fractures had no angulation, the fracture angle was 5° or less 22 fractures had an angulation of $6-10^{\circ}$ and seven of more than 10°. In 16 of these 29 cases the fracture angle had increased by $5.9 \pm 1.3^{\circ}$ during weight-bearing, i.e. during the period between the X-ray examination immediately after the first PTB-cast had been applied and the final examination The largest angulation was 31°, it had increased 20° during weight-bearing. This patient was 60-years old and refused to have the angle corrected. The second largest angulation was 15°, shown in Fig 12. - In five fractures the angle was open anteriorly, in eight medially (varus) and in 11 antero-medially In three fractures the angle was open posteriorly, in one posterior-medially and in one posterior-laterally. - Five of the fractures with angulation of more than 5° were longitud nal (one with encircling wire, two Rush-pins, one screwed, and one without osteosynthesis and with a non-fractured fibula), and 24 were transverse (19 with Rush pins and five without osteosynthesis of which three had a non-fractured fibula).

(12) Rotational deformity Malrotation was observed in four fractures but did not seem to cause any complaints The largest malrotation was 30° in a 73-year old man and the next largest 20° in a 70-year old woman, permanently confined to a long-term institution

(13) Over-all classifications of the final results (Table XXI) The over-all results in this series of 105 fractures evaluated were 67 % excellent, 24 % good, 6 % acceptable and 3 % poor However, as expected, the over-all results in the non-displaced fractures were uniformly excellent The results in the 91 displaced fractures were 57 excellent, 24 good, 7 acceptable and 3 poor - The results at re-examination of the 17 fractures which had not been subjected to early weight-bearing are shown in the list of coded data The functional result in this group was sometimes impossible to evaluate because of other disease and injury Of the three fractures which by "mistake" were not subjected to early weight-bearing two would had been classified as excellent and one as good

Table XXI.

Over-all results at follow-up of tibial shaft fractures

Type of fracture	Excellent	Good	Acceptable	Poor	Total
Displaced longitudinal closed	[illegible]	7	3	1	23
Displaced longitudinal open	2	3			5

Displaced transverse open	17	5	4	1	27
Non-displaced transverse closed	13	1			14
Total	70	25	7	3	105
%	(67%)	(24%)	(6%)	(3%)	

V DISCUSSION

A useful program for treatment of tib al fractures should be applicable to the majority of these fractures but it need not include fractures with severe soft tissue problems due to arterial injury, nerve injury, extensive skin damage, etc and it need not include patients with multiple injuries. Based on the morbidity observed here, the program tested in this investigat on was applicable to some 90 % of all cases of fracture of the tibia in adults Furthermore, the program for treatment of tibial shaft fracture should be sufficiently simple not to require specialized experience, because the everyday run of tibial shaft fractures are treated in peripheral hospitals, complications following treatment with the AO-compression methods have been explained as due to insufficient expertise (Thunold et al 1975) The program should ensure a low incidence of complications, especially serious complications, it should require as few active interventions as possible, short hospitalization and minimal convalescence, and the end result should compare with more complicated methods

The results of this investigation will be compared here with Edwards s (1965) prospective series (the Malmö series), and Olerud and Karlström s (1972a) five year material of tibial shaft fractures treated with the AO-compression plate (the Uppsala series) I have chosen these materials for comparison because they are recent, and they are based on similar demographic and epidemiologic environments In fact, the composition of the three series is almost identical with a dominance of high energy fractures caused by traffic accidents However, in the Malmö series there was an overrepresentation of extensi ve soft tissue injury, referred from a wide area The Uppsala series did not contain a similar proportion of severe soft tissue injury, perhaps because Olerud and Karlström (Olerud 1973, Karlström and Olerud 1975) preferred to use transfixation with the Vidal-Adrey method in such cases However, the classification of soft tissue injury in the Uppsala series differs from that used in the Malmö series and in this investigation a close comparison with the Uppsala series is therefore not feasible

In principle the primary treatment in the Malmö series was the same as here, a comparison between these materials should show whether early weight-bearing in the PTB-cast had an influence on the end result The therapeutic principles applied to the Uppsala series, on the other hand, were entirely different, a comparison should permit an analysis not only of the end results but also of the ent re healing course It would have been desirable to compare these series with a series of tibial shaft fractures not subjected to open treatment but only to early weight-bearing However, the series of cases published by Dehne et al (1961), Brown and Urban (1969), Sarm ento (1967, 1970, 1974).

Broström and Eriksson (1970), Lambding (1973), Balkfors (1974), Burkhalter and Protzman (1975), King (1975), Wiedmer and Bianchini (1975), Rosentahl et al (1977), Suman (1977) were either selected or subjected to incomplete follow-up, they have not been described in sufficient detail to permit more than isolated comparisons

Complications

In this series the majority of the complications were moderate, they did not require secondary interventions and they did not prolong the periods of hospitalization or treatmen Serious complications, to be discussed here, are thrombosis, embolism, deep infection with osteomyelitis, and delayed union requiring secondary operations The incidence of serious complications in this material was 14 % with 6/37 in closed transverse fractures and 4/27 in open transverse fractures By comparison with the Uppsala series, the total absence of osteomyelitis in this series was significant ($p < 0.05$) and this was true also of the total number of complications ($p < 0.05$) even though the definition of delayed union used here probably was somewhat stricter than the one used in Uppsala, in the Uppsala material about 1/4 of the patients were not allowed full weight-bearing until after 20 weeks

(1) Thrombosis and embolism Thrombosis was not recorded in the Malmö, Uppsala and Sarmiento (1974) series of 482 fractures However, several authors (Hjelmstedt and Bergvall 1968, Nylander and Semb 1972, Vogl et al 1972) have shown by phlebography that the incidence of deep thrombosis is high indeed in tibial fractures Hjelmstedt and Bergvall (1968) found an incidence of 54 % in patients over 25 years with a significantly higher incidence in patients treated with internal fixation and a plaster cast as compared to those treated with a cast only Vogl et al (1972) found a lower incidence of deep thrombosis, like Olerud and Karlström (1972a) they treated the fractures with vacuum drainage and early motion Possible the drainage and early motion in the Uppsala series explains the virtual absence of thrombo-embolism recorded there, whereas in this series the incidence was 5 % ($p < 0.01$) However there was no difference between the Uppsala series and this series as regards the incidence of ankle or lower-leg oedema in the Malmö series this sequel to deep thrombosis was not recorded separately and Sarmiento (1974) has not published any follow-up of his patients

In this series the patients did not receive any prophylactic treatment against thrombosis Because of the high incidence of thrombo-embolism in fractures of the hsaft of the tibia and because of the common complaint of a chronic swelling following these fractures routine treatment with Macrodex[R] (Bergentz 1975) should perhaps be recommended in patients over 20 years of age The severity of the fracture does not necessarily indicate the need for such prophylactic treatment, two of the thrombo-embolism cases in this series were non-displaced transverse fractures in patients aged 24 and 44 years

(2) Osteomyelitis In this series osteomyelitis did not occur and in the Malmö series only one case occurred in 109 displaced transverse fractures By contrast, in the Uppsala series the over-all incidence of osteomyelitis was 5 % and of 'metallosis' 10 % The majority of the osteomyelitis cases occurred in the transverse fractures and in particular among the 38 open transverse fractures, 6 of which had this complication The marked difference in incidence of osteomyelitis between this series and the Malmö series on one hand and the Uppsala series on the other is probably related to soft tissue and skin injury, after the skin has been exposed to high energy trauma it does not tolerate the additional injury associated with the exposure for plate osteosynthesis (Edwards 1965, Bauer and Hulth 1973)

The conservative attitude toward the handling of skin and soft tissues basic to this investigation has been applied in earlier materials, e g Zucman and Maurer (1969, 1970), Merle d Aubigné et al (1974), Lottes (1974), Harvey et al. (1975). These materials also had a low incidence of osteomyelitis With the reservation that the distinction between wound infection and osteomyelitis was not always clearly defined, the incidence of wound infection in open fractures seemed to be somewhat higher than in this and in the Malmö series.

(3) Delayed union The concept "delayed union' is hard to define, the time limit of 20 weeks (Nicoll 1964) represents more a conventional than a biologically meaningfull parameter The time limit 20 weeks may still be useful, first to permit a comparison with other materials, and second, e g in this investigation, as an indication when unnecessarily prolonged treatment may be avoided by institution of secondary procedures

The proponents of early weight-bearing in the treatment of fractures of the tibia have always argued that the healing course is promoted by such more physiological treatment (Borelius 1894, Gurd 1940, Dehne 1974, Sarmiento 1974) However, the analysis or presentation of fracture materials treated by early weight-bearing does not seem to permit this conclusion Sarmiento (1967, 1970, 1974) has published values for the mean healing time in different types of tibial fractures but not the incidence of delayed healing In his 1974 publication he had only two cases of pseudarthrosis in 482 fractures In the series of open fractures of the tibial shaft treated with early weight-bearing, published by Brown and Urban 1969, the time in plaster was longer than 20 weeks in 23 of 63 cases Rosentahl et al (1977) treated 60 open tibial fractures with early weight-bearing, a pseudarthrosis operation was performed in ten of these cases, six of whom, however, were infected Nicoll (1964) has carefully studied the incidence of delayed healing in a series of tibial fractures treated with closed methods without weight-bearing, he found an incidence of delayed union of 21 % in non-infected displaced fractures, ranging from 9 % in simple fractures to 39 % in severe fractures In this series the incidence

Brostrom and Eriksson (1970), Lambding (1973), Balkfors (1974), Burkhalter and Protzman (1975), King (1975), Wiedmer and Bianchini (1975), Rosentahl et al. (1977), Suman (1977) were either selected or subjected to incomplete follow-up, they have not been described in sufficient detail to permit more than isolated comparisons

Complications

In this series the majority of the complications were moderate, they did not require secondary interventions and they did not prolong the periods of hospitalization or treatment Serious complications, to be discussed here, are thrombosis, embolism, deep infection with osteomyelitis, and delayed union requiring secondary operations The incidence of serious complications in this material was 14 % with 6/37 in closed transverse fractures and 4/27 in open transverse fractures. By comparison with the Uppsala series, the total absence of osteomyelitis in this series was significant ($p < 0\ 05$) and this was true also of the total number of complications ($p < 0.05$) even though the definition of delayed union used here probably was somewhat stricter than the one used in Uppsala, in the Uppsala material about 1/4 of the patients were not allowed full weight-bearing until after 20 weeks

(I) Thrombosis and embolism Thrombosis was not recorded in the Malmö, Uppsala and Sarmiento (1974) series of 482 fractures. However, several authors (Hjelmstedt and Bergvall 1968, Nylander and Semb 1972, Vogl et al. 1972) have shown by phlebography that the incidence of deep thrombosis is high indeed in tibial fractures. Hjelmstedt and Bergvall (1968) found an incidence of 54 % in patients over 25 years with a significantly higher incidence in patients treated with internal fixation and a plaster cast as compared to those treated with a cast only Vogl et al (1972) found a lower incidence of deep thrombosis, like Olerud and Karlstrom (1972a) they treated the fractures with vacuum drainage and early motion. Possible the drainage and early motion in the Uppsala series explains the virtual absence of thrombo-embolism recorded there, whereas in this series the incidence was 5 % ($p < 0\ 01$) However, there was no difference between the Uppsala series and this series as regards the incidence of ankle or lower-leg oedema in the Malmö series this sequel to deep thrombosis was not recorded separately and Sarmiento (1974) has not published any follow-up of his patients

In this series the patients did not receive any prophylactic treatment against thrombosis Because of the high incidence of thrombo-embolism in fractures of the hsaft of the tib a and because of the common complaint of a chronic swelling following these fractures, routine treatment with Macrodex[R] (Bergentz 1975) should perhaps be recommended in patients over 20 years of age The severity of the fracture does not necessar ly indicate the need for such prophylactic treatment, two of the thrombo-embolism cases in this series were non-displaced transverse fractures in patients aged 24 and 44 years

Table XXII

Fracture healing times (months)

Type of fracture	This series 50%	This series 95%	Malmö series 50%	Malmö series 95%	Brown, Urban (1969) 50%	Brown, Urban (1969) 95%
Displaced longitudinal	2 8	4 3	2 2	3 5		
Displaced transverse closed	3 1	4 8	3 1	9 0		
Displaced transverse open	3 4	5 9	4 5	14 0	4 2	8 2

The Malmö series refers to the prospective series published by Edwards (1965)

In my opinion the weight of evidence suggests that early weight-bearing may have a favourable effect on the healing of fracture of the shaft of the tibia However, early weight-bearing certainly does not guarantee healing

Secondary operations

The incidence of secondary operations in this series (11 %) was significantly (p<0 01) lower than in the Uppsala series (22 %) but the same as in the Malmö series (13 %) The relatively high incidence of secondary operations in the Uppsala series correlates with the incidence of complications common in fractures treated with the compression plate, notably osteomyelitis, broken plates and refractures

Hospitalizat on periods (Table XXIII)

The periods of hospitalization in this series were shorter (p<0 05 for longitudinal and transverse open fractures, p<0 01 for transverse closed fractures) than in the Uppsala series, notably in the transverse closed fractures in which the median period of hospitalization in the Uppsala series was three times as long as in this series, this difference is explained by the relatively high incidence of secondary operations in the Uppsala series However, the hospitalization periods were short in this series also when compared to the Malmö prospective series even though both series had a low incidence of complications At least in part, the difference between this series and the Malmö series may be due to the general trend toward shorter periods of hospitalization during the 15 years which have elapsed between the two ser es

The philosophy basic to this series included the aim of provid ng definitive treatment as early as poss ble, preoperative traction was rarely used The majority of cases subjected to internal fixation were operated on within 24 hours (Table IX). As regards utilization of hosp tal beds the program for treatment used in this series would thus be

of non-union was 14 %, i.e. significantly ($p < 0.05$) lower than in the Nicoll (1964) series.

Edwards and Nilsson (1965) analysed the course of healing in the Malmö series by graphic probit analysis, the regression line for the course of healing obtained with this method does not suffer from undue influence of isolated extreme values. The healing times in this series were compared to those in the Malmö and Brown and Urban (1969) series (Table XXII). In longitudinal fractures the healing times were significantly ($p < 0.01$) shorter in the Malmö series than in this series. The explanation for this may be that the proportion of fractures subjected to stable osteosynthesis with screws was higher in this series, following stable osteosynthesis the clinical evaluation of the fracture healing is difficult, little visible callus is formed, and therefore the period of plaster cast fixation was rarely shorter than 12 weeks

As regards healing time in the displaced transverse fractures there was no difference between the Malmö and this series in terms of 50 % healing, but a difference in 95 % healing This difference was largest in the open fractures where the 95 % healing time in this series was only half of that of the Malmo series. This difference may be due to the higher proportion of large skin wounds in the Malmö series The data were corrected for this difference by exclusion from the Malmo series of all fractures with wounds larger than 10 cm, the 50 % and 95 % healing times in the Malmo series were now calculated to be 4.2 and 9.9 months, still longer than the 3.4 and 5.9 months values recorded in this series When the Brown and Urban (1969) series of open fractures was subjected to the same probit analysis a similar pattern was observed, the 95 % healing time was shorter than in the Malmö series in spite of the fact that the Brown and Urban cases were war injuries with probably more comminution and more extensive soft tissue injury than in the Malmö series of civilian fractures This comparison of the Brown and Urban (1969) and this series with the Malmo series would indicate that early weight-bearing does indeed shorten the healing time However, in a series of 97 tibial fractures treated with closed methods and early weight-bearing in a PTB-plaster, Balkfors (1974) did not find any difference in healing times as compared to the Malmö series. This observation need not be valid because the treatment with PTB-cast was handled by a large number of surgeons and the patients were evaluated at six week intervals (Balkfors 1977)

Analysis of the variance of healing times for displaced transverse fractures revaled a significant ($p < 0.05$) difference between this series and the Malmo series for open as well as closed fractures However, if the eleven cases with major soft tissue wounds in the Malmo series are discounted, the difference between the two series for open transverse fractures has only borderline significance

Results of follow-up

Final evaluation of the treatment of fracture of the tibia must take into account both functional and anatom c parameters, if the two are confused evaluation is invalidated Moderate shortening and/or angulation usually does not cause any inconvenience or impaired function In terms of function it would thus not be reasonable to avoid such anatomic imperfections at the risk of a higher incidence of serious complications. Osteosynthesis with a compression plate is advocated in order to achieve a better end result than that obtainable with closed reduction and plaster (Olerud and Karlström 1972a) Whether this can indeed be ach eved will be d scussed here on the basis of a comparison of this series with the Uppsala series

(1) Jo nt stiffness The proponents of compress on plate osteosynthesis bel eve that primary plaster fixation causes jo nt stiffness, especially in the ankle (Müller et al 1970, Olerud and Karlström 1972a, Karlström and Olerud 1974) However, the incidence of joint stiffness was nearly the same in the Uppsala series as in th s series. On the other hand in this series the stiffness was usually located below the astragalus which was never observed in the Uppsala series At any rate, some residual ankle jo nt stiffness seems to be common following tibial fracture probably due to ischaemic muscle damage (Ellis 1958 Owen and Tsimboukis 1967, Karlström and Olerud 1974, Karlström et al. 1975) i e. the compartment syndrome (v de infra) rather than an effect of plaster fixation on the joints per se The res dual cavus deform ty of the foot, which severely impairs function, has been thoroughly analyzed by Karlström et al (1975)

(2) Atrophy There was no difference between th s series and the Uppsala series as regards muscle atrophy Poss bly early we ght-bearing stimulates muscle function to the same degree as does early motion

(3) Shortening The use of early we ght-bearing has been criticized as a cause of shorten ng n fractures of the tibia Sarm ento (1974) has demonstrated that early weight-bear ng does not increase the n t al shortening When the initial shortening is not deemed acceptable he has recommended transfixation to restore the length Brown (1974) was more conservat ve he felt that shortening was a small price for obtaining uncomplicated healing Dehne et al (1961) exam ned the shortening in a 12 % sample of h s tib al fractures, 2/5 of these fractures had a shorten ng of 1 3 - 1,9 cm

The reason to perform an osteosynthesis in th s ser es was to decrease the final shortening Accepting Sarm ento s (1974) statement that without osteosynthes s the final shortening equals the in t al shorten ng these variables were measured In the long tudinal fractures treated w th screws the mean ga n was 9 mm and the maximal gain 20 mm In the short

preferable to the one published by Olerud and Karlström (1972b) which requires first open reduction and osteosynthesis with a compression plate, and then, as a secondary operation removal of the plate and medullary nailing Other examples of seemingly unnecessary prolongation of the hospitalization period are the recommendations to perform delayed internal fixation (Solheim 1973, Smith 1974, Allgöwer 1975, Langård and Bø 1976, Jensen et al 1977), apparently in an attempt to avoid the high incidence of complications following early primary osteosynthesis with the compression plate in high energy fractures

Table XXIII

Days of hospitalization for tibial shaft fractures, median values

Type of fracture	This series	Uppsala series	Malmö series
Displaced longitudinal	6	12	14
Displaced transverse closed	6	20	14
Displaced transverse open	7	18	35

The Malmö series refers to the prospective series published by Edwards (1965)
The Uppsala series refers to Olerud and Karlström (1972a)
The periods of hospitalization shown here include secondary treatment

Disability periods

The period of disability is an uncertain and poor measure of the results of treatment of fractures of the tibia, even comparisons in the same community and during the same period of time may be invalid because of undefinable circumstances As compared to this series, the Uppsala series had a somewhat higher number of patients back to work within six months but somewhat fewer at 12 months There was not much difference in this respect between this series and the Malmo series except in open transverse fractures, at 12 months 2/3 of the patients here had returned to work and only about one half in Malmö, this difference was significant ($p < 0.05$) but may be due to the higher incidence of extensive soft tissue injury in the Malmö series

With due regard to the difficulties in comparing disability periods the data discussed here may indicate that rehabilitation in non-complicated cases of compression plate treated tibial fractures is somewhat more rapid than in those treated in a plaster cast However, the higher incidence of complications following compression plate fixation results in an increased number of patients with very long periods of disability

Results of follow-up

Final evaluation of the treatment of fracture of the tibia must take into account both functional and anatomic parameters, if the two are confused evaluation is invalidated. Moderate shortening and/or angulation usually does not cause any inconvenience or impaired function In terms of function it would thus not be reasonable to avoid such anatomic imperfections at the risk of a higher incidence of serious complications. Osteosynthesis with a compression plate is advocated in order to achieve a better end result than that obtainable with closed reduction and plaster (Olerud and Karlström 1972a). Whether this can indeed be achieved will be discussed here on the basis of a comparison of this series with the Uppsala series.

(1) Joint stiffness The proponents of compression plate osteosynthesis believe that primary plaster fixation causes joint stiffness, especially in the ankle (Müller et al. 1970, Olerud and Karlström 1972a, Karlström and Olerud 1974). However, the incidence of joint stiffness was nearly the same in the Uppsala series as in this series. On the other hand in this series the stiffness was usually located below the astragalus which was never observed in the Uppsala series. At any rate, some residual ankle joint stiffness seems to be common following tibial fracture, probably due to ischaemic muscle damage (Ellis 1958, Owen and Tsimboukis 1967, Karlström and Olerud 1974, Karlström et al. 1975) i.e. the compartment syndrome (vide infra) rather than an effect of plaster fixation on the joints per se The residual cavus deformity of the foot, which severely impairs function, has been thoroughly analyzed by Karlström et al. (1975).

(2) Atrophy There was no difference between this series and the Uppsala series as regards muscle atrophy Possibly early weight-bearing stimulates muscle function to the same degree as does early motion

(3) Shortening The use of early weight-bearing has been criticized as a cause of shortening in fractures of the tibia. Sarmiento (1974) has demonstrated that early weight-bearing does not increase the initial shortening. When the initial shortening is not deemed acceptable he has recommended transfixation to restore the length Brown (1974) was more conservative, he felt that shortening was a small price for obtaining uncomplicated healing. Dehne et al (1961) examined the shortening in a 12 % sample of his tibial fractures, 2/5 of these fractures had a shortening of 1,3 – 1,9 cm

The reason to perform an osteosynthesis in this series was to decrease the final shortening. Accepting Sarmiento s (1974) statement that without osteosynthesis the final shortening equals the initial shortening these variables were measured. In the longitudinal fractures treated with screws the mean gain was 9 mm and the maximal gain 20 mm. In the short

preferable to the one published by Olerud and Karlström (1972b) which requires first open reduction and osteosynthesis with a compression plate, and then, as a secondary operation removal of the plate and medullary nailing Other examples of seemingly unnecessary prolongation of the hospitalization period are the recommendations to perform delayed internal fixation (Solheim 1973, Smith 1974, Allgöwer 1975, Langård and Bø 1976, Jensen et al 1977), apparently in an attempt to avoid the high incidence of complications following early primary osteosynthesis with the compression plate in high energy fractures

Table XXIII

Days of hospitalization for tibial shaft fractures, median values

Type of fracture	This series	Uppsala series	Malmö series
Displaced longitudinal	6	12	14
Displaced transverse closed	6	20	14
Displaced transverse open	7	18	35

The Malmö series refers to the prospective series published by Edwards (1965)
The Uppsala series refers to Olerud and Karlström (1972a)
The periods of hospitalization shown here include secondary treatment

Disability periods

The period of disability is an uncertain and poor measure of the results of treatment of fractures of the tibia, even comparisons in the same community and during the same period of time may be invalid because of undefinable circumstances As compared to this series, the Uppsala series had a somewhat higher number of patients back to work within six months but somewhat fewer at 12 months There was not much difference in this respect between this series and the Malmö series except in open transverse fractures, at 12 months 2/3 of the patients here had returned to work and only about one half in Malmö, this difference was significant ($p < 0.05$) but may be due to the higher incidence of extensive soft tissue injury in the Malmö series

With due regard to the difficulties in comparing disability periods the data discussed here may indicate that rehabilitation in non-complicated cases of compression plate treated tibial fractures is somewhat more rapid than in those treated in a plaster cast However, the higher incidence of complications following compression plate fixation results in an increased number of patients with very long periods of disability

Table XXIV
Progression of deformity in tibial shaft fractures

	<5°	6-10°	>10°
Postoperative	12	17	
After first PTB-cast	12	16	1
After 3 weeks of weight-bearing	4	21	4
After 9 weeks of weight-bearing	2	22	5
Final angulation		22	7

As regards the direction of angulation it appeared that early weight-bearing had a general tendency to cause a varus angle but other types of angulations were also observed There did not seem to be any correlation between fracture level and risk or type of angulation

It appears from this investigation that early weight-bearing is definitely accompanied by a risk for angulation which one should be prepared to prevent and treat actively All angulations should be corrected as early as possible, even those which seem acceptable, after a period of weight-bearing the angle may increase and it may soon prove difficult to correct It is simple to wedge the long-leg cast, especially when the true angle and its direction have been determined There should be no reason to accept an initial angulation of 15° as proposed by Wyman and Barr (1974) In this way the incidence of angulation should decrease considerably Only one of those which developed severe angulation started weight-bearing with a truly straight tibia, this was a proximal fracture with a non-fractured fibula In another two short oblique fractures with non-fractured fibulas the varus angles were corrected by wedging but they recurred when the PTB-plaster was applied and they then increased during weight-bearing

(5) Over-all results (Table XXV) The functional over-all results were similar and generally favourable in the three series compared here It is true that the Uppsala series was somewhat better than the Malmö series but this was very probably due to the high incidence of open transverse fractures in the latter series, after exclusion of the cases with major soft tissue injury (wound size larger than 10 cm) the end results in the Malmö series were comparable to the other series Indeed, if one can achieve a low incidence of complications the funct onal end results seem to correlate more with the initial injury than with the type of treatment It is in fact remarkable that the h gh incidence of complications in the Uppsala series d d not adversely influence the end result, these facts suggest that the infected fractures were treated with a high degree of expertise

oblique and comminuted transverse fractures treated with a Rush-pin the mean gain was [redacted] mm and the maximal gain 34 mm

The reason why osteosynthesis with the Rush-pin did not always prevent shortening was that the pin did not fit the entire circumference of the marrow cavity, a slight dislocation to the side therefore occurred, sometimes associated with shortening in oblique and comminuted fractures (Fig 6)

Moderate shortening is usually not much of a problem if the function is otherwise good It therefore does not seem indicated to subject the patients to an increased risk of complications solely to avoid shortening However, there seems to be no reason to accept shortening if it can be avoided at no or little risk as demonstrated in this series

(4) Angulation At follow-up a high incidence of angulation was recorded This problem seems to have been minimized by the proponents of weight-bearing and was therefore not identified in this investigation until at the time of follow-up Brown and Urban (1969) found an angulation up to 15° in 44 of 63 fractures Dehne et al (1961) measured the fracture angles in 27 consecutive fractures in a total of 221 fractures, twelve of the 27 fractures had angulation, but not more than 10°, the authors concluded that angulation does not constitute a problem but in their figure 2C the angulation measured is about 17° Gamble et al (1972) found angulations of more than 5° in 20 % of their cases Sarmiento (1974) reported 9 % angulation over 5° with maximal angulation of 12° In all of the above publications the angulation has been measured only in AP and lateral X-rays projections, the true angulation may thus have been underestimated

The high incidence of final angulation in this series was not always due to early weight-bearing In seven cases an angulation seen in the immediate postoperative X-ray was caused by undue bending of the Rush-pin before insertion In 18 fractures the angulation increased after the primary treatment and in 16 of those the increased angulation occurred during weight-bearing (Table XXIV) In ten fractures the angle increased less than 4° but in eight fractures it increased more than 7° and up to 23° In three of these latter fractures the angle increased gradually until it was observed only when the fracture had healed (Fig 13), in three fractures the fibula was not fractured, one fracture had very slow healing and one fracture occurred in a patient who was [redacted] chronic alcoholic and left the hospital without waiting for correct on of the angulation which occurred after the long-leg cast had been changed to a PTB-cast

Table XXIV
Progression of deformity in tibial shaft fractures

	<5°	6-10°	>10°
Postoperative	12	17	
After first PTB-cast	12	16	1
After 3 weeks of weight-bearing	4	21	4
After 9 weeks of weight-bearing	2	22	5
Final angulation		22	7

As regards the d rection of angulation it appeared that early weight-bearing had a general tendency to cause a varus angle but other types of angulations were also observed There did not seem to be any correlation between fracture level and risk or type of angulation

It appears from this investigation that early weight-bearing is definitely accompanied by a risk for angulation which one should be prepared to prevent and treat actively All angulations should be corrected as early as possible, even those which seem acceptable, after a period of weight-bearing the angle may increase and it may soon prove difficult to correct It is simple to wedge the long-leg cast, especially when the true angle and its direction have been determined There should be no reason to accept an initial angulation of 15° as proposed by Wyman and Barr (1974) In this way the incidence of angulation should decrease considerably Only one of those which developed severe angulation started weight-bearing with a truly straight tibia, this was a proximal fracture with a non-fractured fibula In another two short oblique fractures with non-fractured fibulas the varus angles were corrected by wedging but they recurred when the PTB-plaster was applied and they then increased during weight-bearing

(5) Over-all results (Table XXV) The functional over-all results were similar and generally favourable in the three series compared here It is true that the Uppsala series was somewhat better than the Malmö series but this was very probably due to the high incidence of open transverse fractures in the latter series, after exclusion of the cases with major soft tissue injury (wound size larger than 10 cm) the end results in the Malmö series were comparable to the other series Indeed, if one can achieve a low incidence of complicat ons the functional end results seem to correlate more with the initial injury than with the type of treatment It is in fact remarkable that the high incidence of complications in the Uppsala series did not adversely influence the end result, these facts suggest that the infected fractures were treated with a high degree of expertise

oblique and comminuted transverse fractures treated with a Rush-pin the mean gain was 8 mm and the maximal gain 34 mm

The reason why osteosynthesis with the Rush-pin did not always prevent shortening was that the pin did not fit the entire circumference of the marrow cavity, a slight dislocation to the side therefore occurred, sometimes associated with shortening in oblique and comminuted fractures (Fig 6)

Moderate shortening is usually not much of a problem if the function is otherwise good It therefore does not seem indicated to subject the patients to an increased risk of complications solely to avoid shortening However, there seems to be no reason to accept shortening if it can be avoided at no or little risk as demonstrated in this series

(4) Angulation At follow-up a high incidence of angulation was recorded This problem seems to have been minimized by the proponents of weight-bearing and was therefore not identified in this investigation until at the time of follow-up Brown and Urban (1969) found an angulation up to 15° in 44 of 63 fractures Dehne et al (1961) measured the fracture angles in 27 consecutive fractures in a total of 221 fractures, twelve of the 27 fractures had angulation, but not more than 10°, the authors concluded that angulation does not constitute a problem but in their figure 2C the angulation measured is about 17° Gamble et al (1972) found angulations of more than 5° in 20 % of their cases Sarmiento (1974) reported 9 % angulation over 5° with maximal angulation of 12° In all of the above publications the angulation has been measured only in AP and lateral X-rays projections, the true angulation may thus have been underestimated

The high incidence of final angulation in this series was not always due to early weight-bearing In seven cases an angulation seen in the immediate postoperative X-ray was caused by undue bending of the Rush-pin before insertion In 18 fractures the angulation increased after the primary treatment and in 16 of those the increased angulation occurred during weight-bearing (Table XXIV) In ten fractures the angle increased less than 4° but in eight fractures it increased more than 7° and up to 23° In three of these latter fractures the angle increased gradually until it was observed only when the fracture had healed (Fig 13), in three fractures the fibula was not fractured, one fracture had very slow healing and one fracture occurred in a patient who was a chronic alcoholic and left the hospital without waiting for correction of the angulation which occurred after the long-leg cast had been changed to a PTB-cast

into open and closed fractures. 43 % of the cases were ski injuries, the good prognosis in this type of fractures is well known (Infanger et al. 1971, van der Linden et al. 1975). In the 95 open fractures 23 severe complications occurred, 11 of these osteomyelitis. Among the open fractures 39 were probably after indirect trauma as the wounds were caused by simple piercing of the skin from within, the majority of the complications probably occurred in the other 56 fractures. It therefore seems reasonable to agree with Olerud's and Karlström's statement that the compression plate method is not suitable as a routine method in tibial shaft fractures (Olerud and Karlstrom 1972a, Karlström 1976)

The compartment syndrome

In this series one patient with a compartment syndrome received adequate treatment by early fasciotomy, the functional end result was excellent. In three patients active treatment of a compartment syndrome was not instituted, all had poor end results. In addition a patient who was never treated with early weight-bearing and PTB-plaster had a comminuted proximal fracture of the tibia with arterial injury, in spite of fasciotomy and repair of the artery he had a Volkmann contracture resulting in a contracted foot, probably because the arterial injury was repaired too late

The compartment syndrome and its serious effect on the end results in fractures of the tibia has been known for a long time and it has been well described in numerous publications (Volkmann 1881, Ellis 1958a, Seddon 1966, Willhoite and Moll 1970, Sundén and Wiberg 1971, Fowler and Willis 1975, Holden 1975, Karlstrom et al 1975, Matsen and Clawson 1975, Rorabeck and MacNab 1976) The importance of treating the compartment syndrome has been well documented (Ernst and Kaufer 1971, Feagin and White 1973, Patman et al 1973, Sheridan and Matsen 1976) and seemingly reliable diagnostic methods based on measurements of the intramuscular pressure have recently been published (Whitesides et al 1975, Matsen et al 1976, Mubarak et al 1976). One may ask why the diagnosis of compartment syndrome is still often not made and even when it is the patients often do not receive adequate treatment. However, it is not easy to routinely measure the intramuscular pressure, it is not enough to measure it once but it should be measured repeatedly or continously and in all the four compartments. There is a great need for simple and routinely useful methods for early diagnosis and treatment of the compartment syndrome This series has confirmed Edwards's (1965) demonstration that osteomyelitis is a virtually avoidable complication in fractures of the tibia. Olerud and Karlström (1972a) have demonstrated that osteomyelitis can be treated so successfully that it does not jeopardize a favourable end result. Intramedullary reaming and nailing has been repeatedly shown to be a reliable method in the treatment of non-union (Christensen 1973) The compartment syndrome remains as the last unsolved threat to uniformly good end results in tibial fractures

One may argue that the over-all evaluation should include also non-symptomatic anatomic imperfections such as angulations In the displaced fractures the sum of all parameters gave 38 % excellent, 46 % good, 13 % acceptable and 3 % poor, the aggregate excellent-good thus was about the same as when function only was evaluated

Few authors have attempted to compare the end results of closed and open treatment of fractures of the tibia in one and the same investigation Karaharju et al (1975) have compared two such groups and their conclusions agreed with the observations here, there was little difference in end result between the two groups but a significant difference in the incidence of complications

Table XXV

Classification of final status at follow-up of displaced tibial shaft fractures

Fracture type	Malmö series	Uppsala series	Present series
Longitudinal			
Excellent-good	41	42	24
Fair-poor	4	1	4
Transverse, closed			
Excellent-good	54	39	35
Fair-poor	8	3	1
Transverse, open			
Excellent-good	32	25	22
Fair-poor	10	6	5
Total			
Excellent-good	127 (85%)	106 (91%)	81 (89 %)
Fair-poor	22 (15%)	10 (9 %)	10 (11%)

The Uppsala series refers to Olerud and Karlström (1972a)
The Malmö series refers to prospective series of Edwards (1965)

The comparisons done here between th s series and the Malmo ser es and the Uppsala series presuppose that the latter represents the AO-compression plate method An analysis of other publications based on that method (Rittman et al 1970 Ketenjian and Shelton 1972, Gallinaro et al 1973 Solheim 1973, Thunold et al 1975) conf rms that the Uppsala series is indeed representative However, it has been stressed that the AO-methods require a techn cal expertise and that the complications are due to technical failures (Thunold et al 1975) The series of fractures from the University Hospital in Basel (Ruedi et al 1975), where the AO-methods are very well known, had a high incidence of serious complications in open fractures The fractures were classified only

into open and closed fractures 43 % of the cases were ski injuries, the good prognosis in this type of fractures is well known (Infanger et al 1971, van der Linden et al, 1975). In the 95 open fractures 23 severe complications occurred, 11 of these osteomyelitis Among the open fractures 39 were probably after indirect trauma as the wounds were caused by simple piercing of the skin from within, the majority of the complications probably occurred in the other 56 fractures. It therefore seems reasonable to agree with Olerud's and Karlström s statement that the compression plate method is not suitable as a routine method in tibial shaft fractures (Olerud and Karlström 1972a, Karlström 1976)

The compartment syndrome

In this series one patient with a compartment syndrome received adequate treatment by early fasciotomy, the functional end result was excellent. In three patients active treatment of a compartment syndrome was not instituted, all had poor end results In addition a patient who was never treated with early weight-bearing and PTB-plaster had a comminuted proximal fracture of the tibia with arterial injury, in spite of fasciotomy and repair of the artery he had a Volkmann contracture resulting in a contracted foot, probably because the arterial injury was repaired too late

The compartment syndrome and its serious effect on the end results in fractures of the tibia has been known for a long time and it has been well described in numerous publications (Volkmann 1881 Ellis 1958a, Seddon 1966, Willhoite and Moll 1970, Sundén and Wiberg 1971 Fowler and Willis 1975, Holden 1975, Karlström et al 1975, Matsen and Clawson 1975, Rorabeck and MacNab 1976) The importance of treating the compartment syndrome has been well documented (Ernst and Kaufer 1971, Feagin and White 1973, Patman et al 1973 Sheridan and Matsen 1976) and seemingly reliable diagnostic methods based on measurements of the intramuscular pressure have recently been published (Whitesides et al 1975 Matsen et al 1976, Mubarak et al 1976) One may ask why the diagnosis of compartment syndrome is still often not made and even when it is the patients often do not receive adequate treatment However, it is not easy to routinely measure the intramuscular pressure it is not enough to measure it once but it should be measured repeatedly or continously and in all the four compartments There is a great need for simple and routinely useful methods for early diagnosis and treatment of the compartment syndrome This series has confirmed Edwards s (1965) demonstration that osteomyelitis is a virtually avoidable complication in fractures of the tibia Olerud and Karlström (1972a) have demonstrated that osteomyelitis can be treated so successfully that it does not jeopardize a favourable end result Intramedullary reaming and nailing has been repeatedly shown to be a reliable method in the treatment of non-union (Christensen 1973) The compartment syndrome remains as the last unsolved threat to uniformly good end results in tibial fractures

Ipsilateral fractures of the femur and the tibia

In this series only four cases had an ipsilateral femoral fracture. Only one of these could bear weight early in a PTB-cast, the femoral fracture was treated by intramedullary reaming and nailing. Another femoral fracture was treated in the same way but the patient had a head injury and an unstable pertrochanteric femoral fracture of the contralateral side which delayed mobilization. One femoral fracture was treated with a compression plate and could therefore not bear full weight (Hansson et al. 1977) and one was treated in traction for six weeks and the patient was then mobilized with a cast brace.

Several authors feel that ipsilateral fracture of the femur constitutes an indication for compression plate osteosynthesis of a tibial fracture (Nicoll 1974, Höjer et al 1977, Karlström and Olerud 1977), early mobilization and better end results would be worth the increased risk of complications However, the PTB-cast allows early motion of the knee and if the femoral fracture permits reaming and intramedullary nailing the patient can be mobilized earlier with full weight-bearing than with a plate osteosynthesis which does not allow weight-bearing.

The discomfort to the patient

Few authors have compared different methods of treatment of fracture of the tibia in term of comfort or rather discomfort to the patients. From the start, this investigation aimed at making Edwards s (1965) method more comfortable to the patient without jeopardizing the end result The majority of the patients tolerated the PTB-cast well it was unpadded but it was applied only after the initial swelling had disappeared In fact, all patients were satisfied with the PTB-cast and a few returned to their occupations in the cast The majority learned to walk with or without a cane A movable knee permits the patient to sit in the back-seat of a car, in the cinema, theater etc Under special circumstances the PTB-cast permits driving a car and a movable knee makes sexual intercourse easier (Brown 1974)

Practical recommendations

1 In order to diminish the risk of shortening by displacement of the fracture ■ thick intramedullary pin should be chosen so that the medullary cavity is adequately filled.

2 Do not bend the pin so much that the fracture angulates forwards, it should be bent only so that it obtains the shape of ■ Kuntscher nail. If it is necessary to bend the distal end of the Rush-pin in order to find the entrance to the medullary cavity in the distal fragment, it is sufficient to bend the last three cm only A thin Kuntscher nail can be used instead of ■ Rush-pin

3 All postoperative angulations should be corrected by wedging the long-leg cast as soon as possible Postoperative malrotation can be corrected by ■ transverse circumcision of the plaster and rotation of the distal fragment within the plaster

4. After the patient has been bearing full weight in the PTB-cast the position of the fracture should be checked by X-ray not later than at two weeks, if the fracture does not have any tendency to angulate further checks can be postponed until every fourth or sixth week

5 The exact angulation should be determined at each X-ray examination, it is not enough by eye measurement alone

6 If the patient is comfortable in the PTB-cast, it need not be changed unless checking for clinical evidence of healing

VI. CONCLUSIONS

On the strength of the material presented here and in the light of earlier publications the following may be concluded concerning the treatment of the vast majority of fractures of the leg in adults.

1. Reduction and osteosynthesis with screw(s) in longitudinal fractures or intramedullary nailing in transverse fractures reduce the risk of shortening of the tibial shaft fracture

2. In longitudinal fractures open reduction and osteosynthesis with screw(s) is associated with but little risk for local complications Screw fixation does not preclude early weight-bearing in the PTB-cast.

3. In transverse fractures closed reduction and intramedullary fixation with a Rush-pin does not increase the risk for necrosis of the skin and osteomyelitis After intramedullary nailing transverse fractures are well suited for early weight-bearing in a PTB-cast.

4 Early weight-bearing in a PTB-cast is recommended as the routine method in the majority of tibial shaft fractures

5 Early weight-bearing may increase the angulation, weight-bearing should not be permitted until angulation has been corrected.

6 Early weight-bearing probably favours healing of transverse fractures

7 The functional end result following early weight-bearing in a PTB-cast compares well with other methods and is more comfortable to the patient

8 The compartment syndrome remains an important practical problem in the treatment of fractures of the leg.

VII. SUMMARY

A. Purpose of this investigation

The purpose of this prospective investigation was to test whether the active primary treatment of tibial shaft fractures practised by Edwards (1965) could be combined with early weight-bearing in the PTB-cast practised by Sarmiento (1967).

B Case Material

The material consisted of 105 patients with 110 fractures of the tibial shaft, 17 fractures were not displaced and 93 displaced. 29 of the displaced fractures were longitudinal of which five were open and 64 were transverse, of which 27 were open. 55 of the displaced fractures were caused by high energy trauma, mainly traffic accidents.

C Treatment

Primary definitive treatment was provided as soon as possible. In 10 fractures the operation was delayed 24 hours or more, mainly because of concomitant injury or disease

(1) Displaced longitudinal fractures. Open reduction and osteosynthesis were performed when the displacement was deemed unacceptable In 18 fractures the osteosynthesis was carried out with screw(s) and in one fracture an encircling wire was used. Ten fractures were reduced by closed methods, in five of these blind intramedullary nailing with a Rush-pin was performed In the five open fractures the wound was closed with primary suture

(2) Transverse fractures Non-displaced fractures and displaced fractures which could be reduced to a stable position were treated with a long-leg cast only If stable fixation could not be obtained blind nailing with a Rush-pin was performed In comminuted fractures where the Rush pin did not give sufficient stability, transfixation in plaster was made - In 18 fractures the displacement was reduced to a stable position without osteosynthesis In 43 fractures fixation was obtained with a Rush pin One short oblique fracture was stabilized with a screw Transfixation was used in two comminuted fractures In all 27 open fractures the wounds were sutured primarily with a relaxing incision in only one fracture Antibiotics were used in all open fractures

(3) Plaster fixation All fractures were initially stabilized with a long-leg plaster, and the patients were mobilized with crutches without weight-bearing as soon as possible

VI. CONCLUSIONS

On the strength of the material presented here and in the light of earlier publications the following may be concluded concerning the treatment of the vast majority of fractures of the leg in adults

1 Reduction and osteosynthesis with screw(s) in longitudinal fractures or intramedullary nailing in transverse fractures reduce the risk of shortening of the tibial shaft fracture.

2. In longitudinal fractures open reduction and osteosynthesis with screw(s) is associated with but little risk for local complications Screw fixation does not preclude early weight-bearing in the PTB-cast

3 In transverse fractures closed reduction and intramedullary fixation with a Rush-pin does not increase the risk for necrosis of the skin and osteomyelitis After intramedullary nailing transverse fractures are well suited for early weight-bearing in a PTB-cast.

4 Early weight-bearing in a PTB-cast is recommended as the routine method in the majority of tibial shaft fractures

5 Early weight-bearing may increase the angulation, weight-bearing should not be permitted until angulation has been corrected

6 Early weight-bearing probably favours healing of transverse fractures

7 The functional end result following early weight-bearing in a PTB-cast compares well with other methods and is more comfortable to the patient

8 The compartment syndrome remains an important practical problem n the treatment of fractures of the leg.

VII. SUMMARY

A. Purpose of this investigation

The purpose of this prospective investigation was to test whether the active primary treatment of tibial shaft fractures practised by Edwards (1965) could be combined with early weight-bearing in the PTB-cast practised by Sarmiento (1967).

B Case Material

The material consisted of 105 patients with 110 fractures of the tibial shaft, 17 fractures were not displaced and 93 displaced. 29 of the displaced fractures were longitudinal of which five were open and 64 were transverse, of which 27 were open. 55 of the displaced fractures were caused by high energy trauma, mainly traffic accidents.

C Treatment

Primary definitive treatment was provided as soon as possible. In 10 fractures the operation was delayed 24 hours or more, mainly because of concomitant injury or disease

(1) Displaced longitudinal fractures. Open reduction and osteosynthesis were performed when the displacement was deemed unacceptable In 18 fractures the osteosynthesis was carried out with screw(s) and in one fracture an encircling wire was used. Ten fractures were reduced by closed methods, in five of these blind intramedullary nailing with a Rush-pin was performed In the five open fractures the wound was closed with primary suture

(2) Transverse fractures Non-displaced fractures and displaced fractures which could be reduced to a stable position were treated with a long-leg cast only. If stable fixation could not be obtained, blind nailing with a Rush-pin was performed In comminuted fractures where the Rush-pin did not give sufficient stability, transfixation in plaster was made - In 18 fractures the displacement was reduced to a stable position without osteosynthesis In 43 fractures fixation was obtained with a Rush-pin. One short oblique fracture was stabilized with a screw Transfixation was used in two comminuted fractures In all 27 open fractures the wounds were sutured primarily with a relaxing incision in only one fracture Antibiotics were used in all open fractures

(3) Plaster fixation. All fractures were initially stabilized with a long-leg plaster, and the patients were mobilized with crutches without weight-bearing as soon as possible

VI. CONCLUSIONS

On the strength of the material presented here and in the light of earlier publications the following may be concluded concerning the treatment of the vast majority of fractures of the leg in adults.

1 Reduction and osteosynthesis with screw(s) in longitudinal fractures or intramedullary nailing in transverse fractures reduce the risk of shortening of the tibial shaft fracture

2. In longitudinal fractures open reduction and osteosynthesis with screw(s) is associated with but little risk for local complications Screw fixation does not preclude early weight-bearing in the PTB-cast

3 In transverse fractures closed reduction and intramedullary fixation with a Rush-pin does not increase the risk for necrosis of the skin and osteomyelitis After intramedullary nailing transverse fractures are well suited for early weight-bearing in a PTB-cast.

4 Early weight-bearing in a PTB-cast is recommended as the routine method in the majority of tibial shaft fractures

5. Early weight-bearing may increase the angulation, weight-bearing should not be permitted until angulation has been corrected

6 Early weight-bearing probably favours healing of transverse fractures

7 The functional end result following early weight-bearing in a PTB-cast compares well with other methods and is more comfortable to the patient

8 The compartment syndrome remains an important practical problem in the treatment of fractures of the leg

I wish to express my gratidue to
Niels Egund for assistance with the radiographic analysis,
David Haffajee for revising the manuscript,
Ingrid Larsson for typing the manuscript,
Bo Nilsson and Klas Svensson for statistical advice,
Anita Nilsson, Ann-Mari Sorensson and Tommy Hansson for making the PTB-casts,
Jan Strömblad and the Phtographic Department for help with the illustrations,
Photographs of the radiograms were made by myself, though.
Claes Westrup for introducing me to the minicomputor.

Financial support was provided by grants from
Alfred Österlunds Stiftelse,
Föreningen för bistånd åt vanföra i Skåne,
Statens medicinska forskningsråd,
Stiftelsen Konsul Thure Carlssons Minne

After 2-3 weeks the plaster was changed to a PTB-cast, if wound healing and swelling permitted. The patients were encouraged to bear full weight in the PTB-cast

D. Complications

There were 20 minor and 15 severe complications. The severe complications were 9 fractures with delayed healing requiring secondary operations and 6 thrombo-embolic non-fatal episodes. There was no case of osteomyelitis in the series.

E. Final Status

In 96 % of the fractures the final status was determined at 1/2 - 3 1/2 years following the accident. The radiographic material was re-examined with regard to malalignment

(1) Function The over-all results were 67 % excellent, 25 % good, 6 % acceptable and 3 % poor. The results in the 91 displaced fractures were 57 excellent, 24 good, 7 acceptable and 3 poor.

(2) Malalignment. The re-examination of the radiographic material revealed a high frequency of angulation. 22 fractures had an angulation of 6-10° and seven more than 10°. In 16 of these 29 cases the fracture angle had increased by $5,9 \pm 1,3^{\circ}$ during weight-bearing. - Shortening of more than one cm was found in 17 fractures

F. Comparison with previous investigations

The results of this investigation were closely compared with Edwards s (1965) prospective series and Olerud and Karlstrom s (1972a)review of tibial fractures treated by AO-compression osteosynthesis There were only small differencies between the three series regarding the final functional status Compared with the AO-series there was a lower frequency of both minor and serious complications, fewer secondary operations and shorter hospitalization times. As in Edwards s series osteomyelitis had been prevented, but the transverse fractures seemed to heal more rapidly

G. Conclusion

It was concluded that the methods of treatment used here give a final result comparable to any other method, but with less discomfort to the patient However, any angulation should be corrected before weight-bearing is permitted The compartment syndrome remains an important practical problem in the treatment of fractures of the leg

AIMS OF THE STUDY

The aims of this investigation were

1 to describe a population of patients with acute and subacute low back pain,

2 to determine whether certain confounding factors irrespective of treatment given, are of any prognostic value when assessing the course of acute and subacute low back pain,

3 to evaluate the effect of three modes of therapy on acute and subacute low back pain

INTRODUCTION

GENERAL ASPECTS

Incidence and economical aspects

The importance of back pain syndromes is due to their high prevalence in the community, and their effect on the individual in terms of pain and disability To obtain a diversified picture of the magnitude of the problem, several factors must be considered, including the frequency in the population, the variations in the course, the age distribution, the number of patients with serious disability and inability to work, and the economic consequences Evaluation of the epidemiology of low back pain is hampered by incomplete statistics and a lack of uniform definitions

Probably up to 80 % of all people will experience back pain to some extent during their active life (Hult 1954, Horal 1969, Nachemson 1976) In most cases the condition is self limiting, with recovery within one month in 70 % and within two or three months in 90 %, while about 4 % seem to have a duration exceeding six months (Horal 1969) Recurrences are frequent, and three or more episodes have been reported in 30 – 70 % of the afflicted patients (Hult 1954, Horal 1969) Although the course is usually benign, the number of severely disabled people is considerable, owing to the general occurrence of the ailment The back pain patients with more than six months' incapacity to work have been found to be comparable in number with those unfit for work due to rheumatoid arthritis and heart trouble (Haber 1971) And it has been reported that of those off work because of back pain for longer than six months, only 50 % will ultimately return to work (McGill 1968) Back pain is most common between the ages of 30 and 55 years (Hult 1954, Horal 1969, Hirsch et al. 1969, Kelsey 1975) Although the long term disability is most pronounced in the older age groups (Haber 1971, Wood & McLeish 1974), it is clear that back pain usually affects man in

his most productive age Hence, back pain occupies a prominent position in the statistics on sick-leave, accounting for 10 – 15 % of all lost workdays in Sweden (Helander 1973) Among manual workers in England the annual absence from work because of back pain is calculated to be about 70 weeks per 100 men employed (Anderson, J A D , 1976)

The economic consequences are based on the fact that 1 % of all workdays are believed to be lost due to back pain (Helander 1973) To this cost the expenses of treatment must be added In England (Wood 1976), in a population of 1 000 persons about 20 each year will consult their general practioner, scarcely 10 will be referred to an orthopaedic clinic, and a little less than one will be admitted to hospital on account of back pain

Etiology and classifications of low back pain

Back pain is a clinical manifestation that can be caused by a variety of known diseases and morphological changes The herniated disc is thought to account for 5 % of all cases (Hirsch 1966) Back pain is occasionally caused by infection, tumours, fractures, osteoporosis, ankylosing spondylitis, rheumatoid arthritis, spinal stenosis and intraabdominal or intra pelvic disease Certain radiological abnormalities with a definite or questionable association with back pain are summarized in Table 1, where some changes not related to back pain are also listed (Nachemson 1976) The majority of back pain patients do not fall into any of the abovementioned categories, and as a rule back pain is a complaint where the underlying pathophysiology is unfortunately unknown Almost every anatomical structure in the motion segment of the spine has been the subject of etiological discussions (Nachemson 1960, Horal 1969)

Morphological changes occur most frequently in the intervertebral disc (Friberg & Hirsch 1949, Nachemson 1971, Jayson & Barks 1973, Rothman 1973), and also in the intervertebral joints (Badgley 1941, Lewin 1964), and in the vertebral body (Vernon Robert & Pirie 1973, Rolander & Blair 1975) The degenerative changes in the intervertebral joints of the lumbar spine, however, appear relatively late in life (Hirsch 1966, Nachemson 1976) For several decades attention has mainly been directed to the intervertebral disc There is a lack of conclusive evidence, but a

Table 1 Radiological abnormalities in the lumbar spine that are of significance for low back pain.

Irrelevant	Single disc narrowing and spondylosis
	Facet arthrosis, subluxation and tropism

	Rethrolisthesis
	Severe lumbar scoliosis (>80°)
	Severe lordosis
Definite	Spondylolisthesis
	Lumbar osteochondrosis (Scheuerman)
	Congenital/traumatic kyphosis
	Osteoporosis
	Marked multiple disc narrowing

(After Nachemson The Lumbar Spine – An Orthopaedic Challenge Spine 1 59, 1976)

number of indirect indications, of a central role of the disc in the etiology of most cases of low back pain (Nachemson 1971) Disc degeneration is a more or less physiological aging phenomenon but it is assured that certain not yet clearly defined stages in the process are of significance for the production of pain syndromes (Nachemson 1971)

The degeneration of the disc includes morphological changes as well as alterations in the content of water, collagen, mucopolysacharides and cells (Friberg & Hirsch 1949, Nachemson 1971, Jayson & Barks 1973, Rothman 1973, Naylor & Shentall 1976, Naylor 1976) The nutrition to

the degenerated disc is by diffusion only and the central parts, especially the boundary zone between the pulpy nucleus and annulus fibrosus posteriorly, are at risk for nutrient defiency (Nachemson et al. 1970, Maroudas et al 1975, Nachemson 1976) The posterior area of the annulus fibrosus is early and frequently the site of radiating ruptures (Friberg & Hirsch 1949, Nachemson 1971, Jayson & Barks 1973), which might facilitate leakage of chemically irritant products and allow them to come into contact with nerve endings (Nachemson 1971) Disc degeneration with herniation has also been found to be accompanied by auto-immunological phenomena (Bobechko & Hirsch 1965, Gertzbein et al. 1975, Bisla et al 1976)

Information on the mechanical properties of the spine is available from measures of intradiscal pressure (Nachemson 1960, Nachemson & Morris 1964, Nachemson & Elfstrom 1970, Nachemson 1976) These studies show that the pulpy nucleus acts hydrostatically, and the whole disc functions as a shock absorber In the back patient increased mechanical load invariably increases the pain Those positions that are known to be painful in connection with low back pain, e g stooping and sitting without support, give the highest intradiscal pressures It has also been shown that the tensile stresses in the posterior part of the annulus can exceed the calculated strength of these fibres during e g a lifting manoeuvre, resulting in ruptures (Galante 1967, Nachemson 1976)

Whether these ruptures in the annulus fibrosus can cause pain is uncertain, but it is an interesting fact that at least 50 % of all attacks of low back pain are reported to start in connection with a minor accident or strenuous movement (Seager 1959, Glover 1960) This finding is also notable considering the occurrence of fractures in the end plate of the disc and subchondral microfractures in the vertebral bodies, which have been demonstrated in recent years (Vernon Robert & Pririe 1973, Rolander & Blair 1975, Hansson 1977) Whether these events in the vertebral bodies are of any clinical importance is not known The role of the increased intraosseous pressure in vertebral bodies in the pain mechanism is also uncertain (Arnoldi 1972)

Since the etiology is not known in most cases of low back pain, the classification of the disease must be based upon symptoms and clinical findings Unfortunately, there is a lack of general agreement as to definitions and the basic terminology

The terminology that has been used in this study corresponds to a classification that has recently been presented to the International Society for the *Study of the Lumbar Spine* (Nachemson & Andersson 1975). This system relates the terminology to symptoms and clinical findings. The duration and the onset of the disease is given as a prefix. In paranthesis after the symptom diagnosis, additional information can be given e g. x-ray findings.

The whole system of classification and the terminology is outlined in Table 2

METHODS OF PHYSICAL THERAPY

A great variety of non-operative treatment methods is used in patients with low back disorders The reason for this is uncertainty about which method to prefer, probably owing to the lack of knowledge regarding the structural changes causing the symptoms

There are only a few controlled studies reported in the literature in which the effect of different treatment methods has been investigated.

Manipulation has been evaluated in two separate controlled studies (Glover et al. 1974, Doran & Newell 1975)

Both show an immediate slight superiority of manipulation as compared to conventional physiotherapy, orthopaedic corsets and analgesic treatment alone These differencies in results disappear after one to three weeks None of the treatments was found to be better than no treatment at all in the long-term perspective There are few statistically valid trials on different forms of traction. Lidström and Zachrisson (1970) demonstrated an improvement in most patients with low back pain and sciatica, following Tru Trac traction and isometrical exercises, compared to active mobilization of the spine with back muscle strengthening. Lind (1974), on the other hand, noted a deterioration among patients with the same diagnosis treated according to the same method Auto-traction was demonstrated in the same study to be significantly superior to bed rest and combined physiotherapy

Table 2. Classification of Low Back Pain. (After Alf Nachemson and Gunnar Andersson: Classification of Low Back Pain, presented to the International Society for the Study of the Lumbar Spine, 1975)

TABLE 1 a

PREFIX

Acute 0 – 2 months' duration

Chronic More than 2 months' duration

Recurring Symptoms recurring after an interval of no symptoms

TABLE 1 b

SYMPTOM DIAGNOSIS

Insufficientia dorsi

Tiredness and light ache or pain provoked by repeated or forceful movements or by some other mechanical stress, e.g. work position or the same work position for a long period of [illegible]

Lumbago

Ache and pain localized to the lumbar region with an eventual radiation over the gluteal region, the hips or the lower part of the abdomen. This syndrome is aggravated in the acute stages by all movements and loads, in the [illegible]

Sciatica

Ache and radiating pain in one or both lower extremities. This is aggravated in the acute stages by all movements and loads to the lumbar spine, in the more chronically ill only by certain movements and loads In most instances the patient needs analgesics. The symptoms can be either acute or set in over a shorter time period. The clinical picture includes numbness, paresthesia and a feeling of weakness in one or both lower extremities.

Rhizopathy

[illegible]

patient has neurologic signs according to the affected segment.

Lumbago sciatica

Symptoms as in both lumbago and sciatica. One of these can dominate the picture.

TABLE 1 c

CLINICAL FINDINGS

Insufficientia dorsi

More rarely pain on palpation in the lumbar spine occurs. There is no increased muscular tension. There is no increased pain on motion of the lumbar spine. No neurologic symptoms. Straight Leg Raising Test will not give pain in the lumbar spine.

Lumbago

Acute Pain on palpation in the back and/or pelvic region. Increased tonus in the lumbar muscles. Definite loss of motion and pain by examination of the motion pattern. No neurologic symptoms. Straight Leg Raising Test might be positive. Straining, coughing, sneezing and similar activities give rise to pain in the back.

Chronic Eventual pain on palpation in the lumbar spine and limitation of motion. No neurologic symptoms. Straight Leg Raising Test can be positive.

Sciatica

[illegible]

motion in the lumbar spine and also sometimes in the hip joint. Straight Leg Raising Test positive. Neurological symptoms occur in rhizopathy (see below).

Rhizopathy

[illegible]

engaged radicular segment

Lumbago sciatica

Clinical findings as in lumbago and sciatica. Either of these can be dominant.

Tumours

Investigations on the curative and preventive effect of strengthening dynamic back exercises (White 1966, Kendall & Jenkins 1968, Lidstrom & Zachrisson 1970) have given discouraging results. These studies have rather supported recommendations of immobilization of the spine for relief of symptoms (White 1969)

None of the above mentioned studies provides the answer to the search for an effective, inexpensive and simple remedy for low back disorders.

In an effort to rationalize the therapy towards these goals, a "Back School" was introduced by Lidstrom & Zachrisson (1973) based on biomechanical and epidemiological studies on low back disorders. This method of treatment is described in detail on page 29 – 31

VOCATIONAL FACTORS

At present there is not enough evidence to confirm an etiologic relationship between low back disorders and mechanical strain on the back. Consequently the true relationship between the effect of specific strain on the low back and subsequent clinical manifestations has not been established

It is widely recognized, however, that an increased load on the already afflicted back produces more pain (Hult 1954, Rowe 1969, Nachemson 1971, Chaffin 1973, Magora 1974)

Measurements of the intradiscal pressure in various postures (Nachemson 1970, Andersson 1974) have shown a similar load on the lumbar spine while standing in a stooped position of 20° as in sitting without support.

These results may be of importance when explaining the outcome of certain studies (Hult 1954, Rowe 1969) on the frequency of low back pain among employees in industry. These investigations indicate that there is no significant difference in the occurrence of low back pain among office employees compared to manual workers. In other studies a significantly higher incidence of back pain is demonstrated among heavy industry workers than among people with less strenuous occupations (Lawrence 1955, Ikata 1965, White 1966, Rowe 1969, Magora 1970, Chaffin 1974).

TABLE 1 a

PREFIX

Acute 0 – 2 months' duration

Chronic More than 2 months' duration

Recurring Symptoms recurring after an interval of no symptoms

TABLE 1 b

SYMPTOM DIAGNOSIS

Insufficientia dorsi

Tiredness and light ache or pain provoked by repeated or forceful movements or by some other mechanical stress, e g. work position or the same work position for a long period of time. The troubles are localized to the lumbar region. The back feels stiff or weak and the patient tries to avoid certain types of stress which he knows will give this feeling of unease.

Lumbago

Ache and pain localized to the lumbar region with an eventual radiation over the gluteal region the hips or the lower part of the abdomen. This syndrome is aggravated in the acute stages by all movements and loads, in the more chronic stages only by certain movements and loads on the lumbar spine. Mostly the patient needs some type of analgesic. The syndrome can set in suddenly or the onset may be over a shorter time period.

Sciatica

[illegible] one or both lower

bar spine, in the more chronically ill only by certain movements and loads In most instances the patient needs analgesics. The symptoms can be either acute or set in over a shorter time period. The clinical picture includes numbness, paresthesia and a feeling of weakness in one or both lower extremities.

Rhizopathy

This is a special form of lumbago sciatica or sciatica characterized by the fact that the radiation of the symptoms in the leg is according to the segmental innervation Most often the patient has neurologic signs according to the affected segment.

Lumbago sciatica

Symptoms as in both lumbago and sciatica. One of these can dominate the picture.

TABLE 1 c

CLINICAL FINDINGS

Insufficientia dorsi

More rarely pain on palpation in the lumbar spine occurs. There is no increased muscular tension There is no increased pain on motion of the lumbar spine No neurologic symptoms. Straight Leg Raising Test will not give pain in the lumbar spine.

Lumbago

Acute Pain on palpation in the back and/or pelvic region Increased tonus in the lumbar muscles. Definite loss of motion and pain by examination of the motion pattern. No neurologic symptoms Straight Leg Raising Test might be positive. Straining, coughing, sneezing and similar activities give rise to pain in the back.

Chronic Eventual pain on palpation in the lumbar spine and limitation of motion. No neurologic symptoms. Straight Leg Raising Test can be positive.

Sciatica

Pain on palpation can occur in the lumbar region and/or the leg No increased tonus in the lumbar musculature There is limitation of motion in the lumbar spine and also sometimes in the hip joint Straight Leg Raising Test positive Neurological symptoms occur in rhizopathy (see below).

Rhizopathy

Clinical findings as in sciatica or lumbago sciatica Straight Leg Raising Test nearly always positive Neurological symptoms commonly positive. Straining coughing, sneezing and similar activities give rise to pain in the engaged radicular segment.

Lumbago sciatica

Clinical findings as in lumbago and sciatica Either of these can be dominant

ficans etc.)

Tumours

The discrepancies that seem to be present between the results presented in the above mentioned investigations may be explained by the various methods of approaching and assessing the same problem. The factors observed to contribute to a high incidence or triggering of low back pain are summarized and listed in Table 3.

Table 3. Factors contributing to the incidence or triggering of low back pain.

Incidence		Triggers
Heavy industry work		Weight lifting
Frequent	lifting	Bending
Occasional	lifting	Rotation
Excessive	bending	
Accidental	bending	
Sudden maximal efforts		
Prolonged postures		
Forceful movements		

The occupational environment is in this study treated as a confounding variable, the influence of which is analysed with reference to prognosis among people with acute and subacute low back pain.

PSYCHOLOGICAL FACTORS

In recent literature the distribution of psychological traits in populations of back pain patients is studied, usually without etiological implications. Westrin (1970) found significant differences regarding several personality traits in a comparison between patients who had been sicklisted for back pain and their matched controls. Psychiatric problems, however, were not more frequent among the back patients, except for cerebrolesional symptoms. In another epidemiological study, Nagi et al. (1973) were able to relate certain indices of emotional and psychological problems to the occurrence of back pain.

Other investigations have yielded further information on the incidence of back pain in specific operations of work (Hult 1954, Ikata 1965, Chaffin 1973) A considerably high incidence of back disorders was disclosed in tasks involving very frequent strenuous lifting. A high incidence was also observed in occupations involving only occasional lifting.

A moderate amount of daily lifting was not found to influence the rate of backache This finding was supported by the results obtained by Magora (1972) who found no relation between lifting and increased incidence of low back pain Similarly, no evidence was found of an association between the occurrence of acute disc herniation and exposure to lifting, demonstrated in a recent case-control study by Kelsey (1975).

Weight lifting is also mentioned to be one of the most common triggers of low back pain Magora (1974) related the subjective assessment of the cause to back pain and the occupation Weight lifting in combination with bending was mentioned to be a very common cause A combination of flexion, rotation and lifting was found to be the most common cause of back injuries at work according to Troup et al (1970)

Other physical operations such as bending, rotation, reaching and sudden maximal efforts are also thought to be connected with a high frequency of back pain (Lawrence 1955, Magora 1973) In accordance with the previous analysis of frequent and rare lifting respectively (Chaffin 1973), only excessive bending or occasional ante-flexions during the day increased the number of back cases (Magora 1973)

Sedentary occupations have also been subjected to attention in a few studies A sedentary occupation, performed for several years, was found to be a significant predisposing factor for acute disc herniation (Kelsey 1975) Similar findings were demonstrated by Kelsey (1975) when studying the association between the driving of motor vehicles and acute disc herniation These observations support previous implications by Magora (1972), in which a higher incidence of back ailments was found in occupations with prolonged sitting (more than four hours daily). Magora (1972) found a similar high rate in occupations involving almost no sitting but mainly standing These results indicate that an occupation allowing a proper amount of variation of postures is preferable to a repetitive work as regards the postures.

groups, one with extremity injuries, and one with back pain. The patients were classified according to physical and psychological ratings. The latter included several inventories, among them the MMPI. Of the two ratings, the psychological one correlated much more strongly to return to work in the back pain group, but not in the extremity injured group. Wifling et al. (1973) tested patients psychologically before spinal fusion was performed. The MMPI discriminated with significance between success and failure, the neurotic triad being found in the failure group. Forrest and Wolkind (1974) described 50 non-operatively treated back patients. They were able to predict the outcome of their treatment using a self-rating scale of psychoneurotic symptoms and behaviour, the Middlesex Hospital Questionnaire. Wiltse and Rocchio (1975) used the MMPI, the Cornell Medical Index and an intelligence test, the Quick test, together with physicians' ratings and biographical data, as predictors of success of chymopapain injection therapy in 130 patients. The MMPI Hs- and Hy-scales were found to be of value. In fact there was a 90 % chance of a good result with very low scores on these scales, but only a 10 % chance when the scores were very high. There were no clinical differences between the high-score and low-score groups. The second best predictor was the physician's own opinion of the patient's psychogenic status. White et al. (1973) found no significant differences in the results of cervical spine fusions in patients with normal and abnormal scores in a psychological inventory, the Cornell Index. An association between back pain and certain psychological traits seems clear on the basis of the reported studies. Some of the studies indicate that populations with and without strong association to these factors have different prognoses. The essential mechanism for this association is obscure, however, and there is a lack of information about the distribution of psychological traits prior to the onset of back pain. Most of the reported studies deal only with chronic cases. It would be of interest, therefore, to study the distribution of the psychological traits and their potential predictive capacity in acute cases.

SOCIAL FACTORS

The literature on back pain in relation to social factors other than purely vocational ones is limited. It is often difficult to define and measure abnormalities in these areas.

The psychological conditions associated with back pain are often evaluated using personality inventories, most frequently the MMPI (Minnesota Multiphasic Personality Inventory) The results in groups of chronic back pain patients are uniform in different studies The hysteria (Hs), hypochondriasis (Hy) and depression (D) scales are elevated, while the other scales are normal or only slightly raised (Hanvik 1950, Beals & Hickman 1972, Sternbach et al 1973, Timmermans & Sternbach 1974, Wilfling et al 1973, Gentry et al 1974, Wiltse & Rocchio 1975) The Hs-, Hy- and D-scales are often referred to as the neurotic triad Not infrequently they form a specific pattern in the MMPI answer sheet, named the "conversion V", with significant rise of Hs and Hy and a slight rise of D There is some confusion in the literature about the stability of these scales in low back pain over a period of time (Phillips 1964, Beals & Hickman 1972, Gentry et al 1974, Wiltse & Rocchio 1975) Sternbach & Timmermans (1975) have shown that the raised neurotic triad has a tendency to become normal after successful rehabilitation The close connection between the experience of back pain and some of the scales in the MMPI is also obvious from the investigations by Ranford et al. (1976) They classified patients with chronic back pain according to their scores on the Hs- and Hy-scales A strong correlation was found between a high value on these scales and a tendency to give an anatomical and "expanded" description of their complaints as visualized in pain drawings Freeman et al (1976) were able to distinguish between three groups of back pain patients an organic, a functional and a mixed group. The three groups differed significantly on several of the scales of the MMPI-test

In a few studies back pain patients have been compared to other groups of patients with regard to psychological factors. Phillips (1964) found that both fracture patients and a group of back patients had higher values on the Hs-, Hy- and D-scales than a group of "normals", but that the differences were more pronounced in the back pain group Similar findings have been reported by Beals et al. (1972) Sternbach et al (1973) compared patients with chronic back pain with a number of patients with rheumatoid arthritis in Steinbrocker's anatomical and functional class II–III The back pain patients were more depressed and more often adopted "an invalid's self concept and life style"

In several investigations the predictive values of psychological factors have been studied in connection with different treatment regimens for back pain Beals et al. (1972) followed the course of 180 patients in two

The company has its own health-centre, divided into a Medical Division, an Industrial Safety Division and a Social Welfare Division. The Medical Division has seven physicians, two physiotherapists and a number of nurses. The health service is directed towards preventive medicine and work related disorders. There is an emergency department to which patients with acute back pain may come for consultation. The investigation was carried out in the health centre by a physiotherapist and an orthopaedic surgeon from the Department of Orthopaedic Surgery I, Sahlgren Hospital, with the assistance of the staff at the centre.

PATIENTS

Criteria for admission to the trial

To be admitted to the trial the patients with low back pain had to meet the following criteria

1. Acute or subacute back pain localized to the lumbosacral region, with or without radiation to the thigh.
2. Duration of pain before entry to the trial not longer than three months.
3. A pain free year before the onset of the current episode.

The criteria for excluding patients were as follows

1. Chronic pain
2. Rhizopathy
3. Pregnancy
4. Back surgery
5. Spondylolisthesis
6. Infections
7. Tumours
8. Ankylosing spondylitis
9. Fractures
10. Senile osteoporosis
11. Structural scoliosis

217 patients were admitted to the trial. All patients were reassessed during the year following the initial examination.

In a few Scandinavian socio-medical investigations on back pain a high incidence of multivarious social problems has been found (Westrin 1970, Natvig 1970, Helander 1973) For example, there is an association between sick-leave for back pain and abuse of alcohol (Lokander 1962, Helander 1973) A high percentage of broken marriages, family problems and financial difficulties has been noted among back patients (Natvig 1970, Westrin 1970) Several authors consider that back pain is associated with a low educational level (Natvig 1970, Westrin 1971, Nagi 1973, Gentry et al 1974), but there is no general agreement on this (Magora 1970), and the association might be caused by a difference in the occupational situation of the less well educated patients

Roslund (1974) found psychological or social problems in almost half of a population of multi-operated back patients He was also able to establish that the prognosis in backsurgery was directly dependent on the presence of psychosocial complications

The investigations quoted point to a link between back disorders and social problems There is, however, a high proportion of chronic cases and individuals with longstanding sick-leave in the reported studies The social conditions represent external circumstances that most probably will be affected by chronic disability and inability to work There is a lack of information as to whether a similar association exists in early, acute, cases and to what degree the occurrence of social problems influences the prognosis in these cases

PROJECT DESIGN

GEOGRAPHICAL LOCATION

This trial was carried out at the Automotive Division of AB Volvo, Goteborg, Sweden There are 13,000 people working in the site of the company where this trial was performed 8,500 are manual workers and 4,500 are clerks and executives The workshops at the plant are mainly engaged in light industrial work with a predominance of assembly line work Most parts of the cars are transported to the Göteborg division from other Volvo factories Hence, there is also a good deal of materials handling at the factory in Göteborg

Questionnaire on vocational factors

This form included questions on the category of employment (office or manual work), the occurrence of shift work and an assessment of the physical and mental load on the patient in his work, using questions that have previously been used by Magora (1972, 1973) The questions included an analysis of the patients working posture (sitting, standing, fixed) and an evaluation of the need for bending, twisting, lifting and forceful movements during the patient's work The need of concentration and the degree of variation during work and possibilities of taking breaks were registered as well as the patient's feelings of fatique and nervousness during work The patient was also asked about his satisfaction with his work and whether he would like to change jobs The questions asked have three alternative answers, listed in Table 4

Questionnaire on socio medical factors

The form listed questions on family conditions (marriage, children and housing, participation in sports activities (yes, no) and physical exercise (>once/week, not regularly, rarely) and the presence of previous or current psychosomatic symptoms (gastric ulcer, gastritis, headaches chest pain)

Forms for the registration of symptoms

Initial assessment

The history of back pain was summarized, and the duration of the current episode was recorded The circumstances of the onset of symptoms were also noted The intensity and quality of pain and the degree of functional limitation were analysed in the following way

A Pain intensity

Screening assessment

Patients consulting the health centre because of low back pain were assessed and screened by the physiotherapist according to the criteria for admission to the trial The patients admitted were at the same time informed about the purpose of the investigation and asked whether they were willing to participate in the trial They were then asked to fill in a psychological test form and a questionnaire regarding their working conditions described in detail on page 23 and Table 4 They were also examined by the orthopaedic surgeon

Initial assessment

Standardized assessment forms for onset-related factors, the intensity of pain, functional limitation, and objective clinical findings were utilized by the physician when examining each patient After being assessed, the patients were allocated at random to one of the three treatments (See statistical methods page 39) The orthopaedic surgeon was in no way involved in any of the treatments given to the patients

Reassessment

After the initial examination the patients were reassessed after ten days three weeks, six weeks, three months, six months and one year On these occasions the same assessment forms were used as when examining the patients initially A few additional questions concerning changes in the clinical picture were, however, added This standardized procedure for interviewing the patients ensured that each patient received an identical examination If any patient recovered before the ten day reassessment, the three week re-examination was excluded Similarly, the six week examination was left out if the patient recuperated after the three week examination This means that the patients were reassessed at least five times and at the most seven times during one year

The patients were asked to choose one of the following descriptions of their pain

1 Terrible pain
2 Intense pain
3 Sharp stabbing pain
4 Spasmodic pain
5 Intense dull aching
6 Slight stabbing pain
7 Slight dull aching
8 Feeling of discomfort
9 Feeling of stiffness
10 Feeling of exhaustion
11 Insignificant pain

The numbers 1 to 5 were pooled into one group under the designation "Intense pain" and the remaining categories were called "Slight pain".

B Functional limitation

The patients were asked about 10 different daily activities (Table 5) For every activity the subject was asked whether he could perform it and, if so, whether it was with or without pain aggravation

Table 5 The inquiry form about difficulties to carry out ten daily activities. Four alternative answers were possible. 1) No difficulties, 2) Painful but possible, 3) Not possible owing to pain and 4) Uncertain.

Walking
Walking in stairs
Running
Stooping over a wash basin
Carrying a bag
Making a bed
Riding in a car
Going to the theatre or cinema
Participating in sports
Sitting for a longer period of time

Table 4 Vocational questionnaire – alternative answers.

	1	2	3
Mechanical stress, postures	**Often**	**Sometimes**	**Rarely**
Sitting, standing	$\geq$ 4 hours/day	2–4 hours/day	< 2 hours/day
Bending, twisting, lifting $\geq$ 5 kg	$\geq$ 10 times/day	< 10 times/day	a few times/day
Lifting $\geq$ 20 kg	> once/hour	$\leq$ once/hour	a few times/day
Forceful movements	$\geq$ 10 times/day	< 10 times/day	a few times/day
Vocational exhaustion			
Back fatigue	never	now and then	daily
General fatigue	none	slight fatigue	daily exhaustion
Nervousness	never	sometimes	daily
Variation, concentration, breaks			
Variation in working tasks	none	repetetive but somewhat varied	varied
Variation in working postures	none	a few fixed postures	optional postures

Environment	good	fair	bad
Colleagues	good	fair	bad
Monotony	varied	fairly varied	monotonous

The patients were asked to choose one of the following descriptions of their pain

1 Terrible pain
2 Intense pain
3 Sharp stabbing pain
4 Spasmodic pain
5 Intense dull aching
6 Slight stabbing pain
7 Slight dull aching
8 Feeling of discomfort
9 Feeling of stiffness
10 Feeling of exhaustion
11 Insignificant pain

The numbers 1 to 5 were pooled into one group under the designation "Intense pain" and the remaining categories were called "Slight pain"

B Functional limitation

The patients were asked about 10 different daily activities (Table 5) For every activity the subject was asked whether he could perform it and, if so whether it was with or without pain aggravation

Table 5 The inquiry form about difficulties to carry out ten daily activities Four alternative answers were possible. 1) No difficulties, 2) Painful but possible 3) Not possible owing to pain and 4) Uncertain.

Walking
Walking in stairs
Running
Stooping over a wash basin
Carrying a bag
Making a bed
Riding in a car
Going to the theatre or cinema
Participating in sports
Sitting for a longer period of time

Table 4 Vocational questionnaire – alternative answers.

	1	2	3
Mechanical stress, postures	**Often**	**Sometimes**	**Rarely**

Breaks	rarely	a few times/day	> once/hour
Concentration required	all day	occasionally	none
Satisfaction			
Working tasks	good	fair	bad
Environment	good	fair	bad
Colleagues	good	fair	bad
Monotony	varied	fairly varied	monotonous

Lateral flexion was measured by plotting one mark on the iliac crest and one mark on a horizontal line through the xiphoid process in the mid axillary line of the trunk The distance between the two marks was measured in standing erect and in maximal lateral flexion The difference of the distances represented the lateral flexion of the spine

Extension was measured by using the same marks as in lateral flexion A thread with a pointed weight was held so that the point of the weight coincided with the lower mark The patient was then asked to bend backwards as much as possible The pointed weight traversed the flank The distance was measured as representing the spinal extension

Rotation was measured with a goniometer with the patient sitting.

Straight Leg Raising test (SLR) was defined as pain in the back when raising passively the straight leg.

The abdominal muscles were tested by the ability to do sit ups The patient was placed in a supine position with his knees flexed at 100° Normal strength of the abdominal muscles was defined as a sit up without using the hands or moving the feet.

The back muscles were tested with the patient in a prone position on the bench of examination The ability to lift the trunk from the bench was defined as normal back muscle strength.

The presence of fixed or impaired gait was registered A neurological examination including sensibility in the legs strength of the great toe extension and patellar and achilles tendon reflexes was carried out At the initial assessment the neurological status was always normal owing to the criteria for the patient selection

Forms for psychological tests

The Hysteria (Hs) and Hypochondriasis (Hy) scales have been isolated from the Minnesota Multiphasic Personality Inventory (MMPI) (Hathaway & McKinsley 1967) These scales will from now on be called the Hs and Hy scales. Earlier experience of this test in studies of low back pain is reported on page 17 19 The isolated scales were modified for a Swedish population by exclusion of certain questions In its modified form the questionnaire comprised 56 questions altogether At the six month ex

C *Quality of pain*

Questions were asked to determine whether the pain was continuous or only felt in connection with movements and strains, and whether it caused sleep disturbances or was aggravated by coughing or sneezing

Reassessment

The patients were asked about the duration of back pain and the duration of sick leave since the last investigation If the initial episode of back pain still persisted, the patient was asked the same questions about pain intensity, functional limitation and quality of pain as in the form used at the initial examination If the patient had developed sciatica, this was also noted If the initial episode had subsided, the patient was asked about relapses and about the occurrence of lumbar insufficiency since the last examination The patient was considered to have an episode of back pain if he had continuous or episodic pain in his back every day, and all patients fulfilled this criterion at entry to the study If he only had a feeling of weakness in his back, or pain only on exertion, not causing daily pain, he was considered to have lumbar insufficiency.

Form for objective findings

The localization of the pain was plotted on a map The presence of postural scoliosis, muscle spasm and pain on palpation and percussion was registered

The range of motion and aggravation of pain in the different planes of motion were registered Flexion, lateral flexion and extension were measured by Schober's modified method, as modified by Moll and Wright (1971)

Flexion was measured by plotting marks on the following locations of the patient's back

1 The lumbosacral junction ("the spinal intersection of a line joining the dimples of Venus")

2 Ten cms above and 5 cms below the lumbo sacral junction

The distance between the upper and the lower marks was measured in standing erect and then in maximal flexion The difference between the distances represented the ability to flex the spine

Analgesics

Only in case of need the patients were provided with analgesics. The choice of analgesics was standardized to either salicylates, paracetamols or a combined analgesic (Doleron® ☆, Astra)

METHODS OF TREATMENT

Back school – M Zachrisson-Forssell

The Back School was put together and initiated by Marianne Zachrisson-Forssell, Registered Physiotherapist, at the Department of Orthopaedic Surgery at Danderyd Hospital in 1970 It is based on research on the etiology of low back pain, intradiscal pressure measurements, EMG, and epidemiological studies

Aims and procedure

The Back School is divided into four 45 minute sessions during a 2 week period under the supervision of a physiotherapist Between 6 and 8 patients participate in each course and all patients are given thorough information about the Back School at their first appointment at the clinic The instruction at the Back School is carried out by means of a sound slide program, "The Back School" A plastic skeleton, flipover charts and other practical aids, such as cleaning materials, boxes, weights etc. are also used

First lesson

The first lesson starts with a presentation of the contents of the whole course and the patients are told that they will be given a test of their knowledge at the end of the course They are told this at an early stage in order to stimulate their active attention

☆ Acid acetylsalicyl., (2-diaethylaminoaethyl.) phenthiazincarboxyl.-(10)-chlorid constit q s. dextropropoxiphen chlorid., coffein, phenazon, constit obd

amination the Eysenck Personality Inventory (Bederoff-Petersson et al 1968) was administered to the patients This inventory included a neuroticism-scale, an extroversion-scale and a lie-scale.

Additional data

The patients' sociomedical circumstances have been further elucidated by information obtained from the social workers employed at Volvo Any contact with the social workers was registered, and whether the contact had occurred before or after 1974, and the reason for the contact was noted

Information about the total amount of sick-listing under various diagnoses during a period of 2 years before entry to the study was obtained for each patient from the National Health Insurance Office (NHIO) The patient's own statement as to his sick-listing for back pain during the time of the study was also checked with the NHIO

"Pain index"

In order to describe changes in pain of the population studied a "pain index" was introduced The "pain index" was based on several of the questions regarding pain as listed in Table 6 The inquiries were provided with scores arbitrarily chosen by the investigators. An attempt was made to range the scores according to the intensity of pain The range of scores of the "pain index" was 0 – 70 points (0 = no pain, 70 p = a maximum of pain)

Table 6 Questions about pain with scores giving rise to the »pain index» The range of scores = 0 – 70 points

	No		Yes
»Intensive pain»	0		15
Sleep disturbing pain	0		5
Continuous pain	0		5
Increased pain when coughing and sneezing	0		5
Increased pain when flexing back	0		10
Increased pain when extending back	0		10
Functional limitation (10 questions, each ranging from 0 – 3 points)	0	–	30

Participation in various types of physical activity and sports is encouraged in order to improve psychological and physical tolerance to pain and stress

Finally, the patients are examined to see how much they have learnt from the course and to give the physiotherapist an opportunity to clear up any misunderstandings

The patients are on the same occasion provided with a written summary of the principal contents of the Back School.

Additionally, patients attending the School are also offered one session of pool exercises under the supervision of the physiotherapist The exercises are individually adjusted to the condition of each patient.

In this trial 70 patients were allocated to the Back School at random None of the patients was absent from any of the four lessons.

The physiotherapist finally made an analysis of the working conditions by visiting the patient's work-site for about an hour The physiotherapist was well acquainted with the working conditions since, before the beginning of the trial, she was doing assembly line work for a considerable time Improper working postures were, when possible corrected The physiotherapist did a follow-up visit at the work site two weeks later, for about half an hour to see whether the patients still succeeded in following the instructions given

Certain tasks of work could not be carried out in proper working postures owing to the construction of the work site Suggestions were then made to the work managers on adjusting the work sites in order to improve the working conditions for the back patients.

If immediate changes were not possible, attempts were made to transfer the patients to another work site if the condition of the back so required

Ten patients changed occupation during the year of observation owing to their back disorders

Combined physical therapy — B Malmstrom, A Zellman

The patients in the combined physical therapy group were treated by registered physiotherapists specially trained in manual therapy This therapy is based on methods developed by Dr J Cyriax (1959), England (general diagnosis), the Norwegian physiotherapist F Kaltenborn (1975) (examination and treatment) and dr Karel Lewit (1977), Czechoslovakia

Different aspects of back disorders are discussed, including their occurrence and which patients suffer pain and when, and it is emphasized that many people have the symptoms periodically The patients are given full details of the anatomy and function of the back and the results of research and studies on back pain Various methods of treatment are discussed and the body's natural capacity for healing is emphasized The fact that decreased strain on the back somewhat relieves the painful back is also emphasized It is also stressed that increased strain on the tissues gives an increase in symptoms It is therefore, important that the patients learn, right from the beginning, the most restful position during rest, the Semi Fowler position The entire instruction, therefore, takes place in this position instead of in the seated position which in itself is a more strenuous position for the back

Second lesson

During the second lesson the mechanical strain in different positions and during different movements is discussed and the influence of the centre of gravity on the strain on the back is explained The function of the muscles and their influence on the back is demonstrated The patients are instructed in isometric abdominal muscle exercises and encouraged to continue these exercises, as the only "programme of home exercises", every day for the rest of their lives (The exercises take 40 seconds to perform) Back muscle exercises are discussed and the patients are told that these exercises expose the back to increased strain, with a risk of aggravation of the symptoms

Third lesson

The third lesson consists of practical application of the previously acquired theoretical knowledge and is the most important part of the Back School in order to give the patient the confidence needed to eliminate factors unfavourable to his back

Two common unfavourable working postures are analysed in detail In the seated

The patients are asked to describe their own work situations and the group endeavours to arrive at a more suitable solution for each individual

Special attention is devoted to lifting techniques Strong leg muscles are a prerequisite for consistent use of a correct lifting technique i e with the knees bent Exercises for strengthening the leg muscles are therefore included

In order to enable the patients to get into and out of bed even during periods of acute pain, they are also trained in this manoeuvre Patients are instructed to rest on their beds in the Semi-Fowler position frequently during acute back pain and to avoid strain

Fourth lesson

The fourth and final lesson mainly consists of encouraging the patients to increase their level of physical activity during leisure hours in spite of their back disorder The advantages of starting physical training in water are emphasized The supportive effect of water contributes to a relief of pain and its constant resistance is regarded for fitness training

Sitting

The position of the spine is checked once again and tests are carried out to see whether any scoliosis due to leg shortening disappears and whether the patient can sit up straight or adopts a special posture due to pain The rotation of the upper half of the body with the pelvis fixed is also investigated The patient sits astride the treat ment bench The rotation is tested actively, passively and against resistance The main factor investigated in the passive tests is whether the spine permits a slight ad ditional elastic stretching in the extreme position Pain in any rotational direction shows which movement should be avoided during the investigation, particularly in the lateral position

Prone

Kibler's test is the first test performed in this position A fold of skin on each side of the spinal process is "rolled up" the spine between the thumbs and index fingers. A positive finding (a distinct change in consistency of the skin, with or without pain) suggests engagement of the corresponding segment, dermatome, myotome, or sclero- tome A springing test for control of the elasticity between the vertebrae is also per formed The index and middle fingers are placed stepwise over the transverse process of each vertebra. With the other hand placed over the fingers, light pressure is applied in the ventral direction Positive Kibler's test findings, such as a dermatome, myo- tome or sclerotome, will now be discernible A "normal' elasticity between the ver tebrae in spite of pain is a stronger indication of a myotome if several pairs of verte brae are engaged and the muscle itself feels hard A dermatome is more local and shows segmental extension Lack of elasticity between one or more lumbar vertebrae must be further investigated in the lateral position

Hyper or hypomobility in the iliosacral joints is investigated Manual pressure is ap- plied distally over the sacrum in the ventrocranial direction and the two iliosacral joints are palpated alternately and compared Slight elasticity should normally be detectable between the edges of the joint surfaces If hypomobility is present the joints feel inelastic and hard and they are usually painful. The *hypomobility in the* iliosacral joint can be confirmed by passively lifting one leg during simultaneous fix ation of the sacrum If the leg on the same side as the suspected hypomobile iliosac- ral joint feels heavier and cannot be lifted up as high as the other leg, the findings are positive This is known as Mennell s test

In hypermobility the elasticity in the joint is considerably increased and is often as sociated with pronounced pain

The above tests for hyper and hypomobility place great demands on the therapist's palpation sensitivity

Any tension in the piriform muscle or pain from the origin of the iliac muscle is pal- pated The psoas and rectus femoris muscles are investigated to see whether they are shortened or contracted due to pain

According to Janda the function of the above muscles is mainly [illegible]
react to incorrect [illegible]
is tested in the [illegible]
iliosacral joints [illegible]
the leg and exte[illegible]
elasticity of the [illegible]

(especially the pelvic examination and diagnosis). Where this was adequate, the patients in this group were treated with manual therapy and in accordance with the methods developed by Dr V. Janda (1975), Czechoslovakia, who has made special studies of the muscular system. He has concentrated his attention to the muscles with mainly postural function and which contract as a result of incorrect movements and strain. He also refers to muscles with mainly phasic function and which react with inhibition and weakening. According to Janda, these incorrect muscle movements often lead to back symptoms.

The patients were also given a five minute information on lifting technique and on the importance of avoiding strenuous movements.

Methods of examination

The treatment is based on a thorough investigation in order to be able to arrive at as specific a diagnosis as possible on the basis of the various tests described below.

The investigation comprises the active and passive mobility in the patient's back and adjacent joints and also isometric muscle tests. The treatment given depends on which structure or structures (muscles, joints, ligaments or discs) that cause(s) the symptoms.

The patient is investigated standing up, sitting with his pelvis fixed, lying prone, supine, and in the lateral position.

Standing

The patient is undressed and inspected from the front, back and side for control of static posture, any difference in leg length, the position of the pelvis, lordosis-kyphosis-scoliosis, and the position of the head and shoulders. Walking on the toes and heels and Trendelenburg's test are also carried out. The patient is asked to lean backwards, sideways and forwards until pain occurs for control of the curvature of the spine, investigation for scoliosis and lateral deviations when leaning forward due to pain The spine is also investigated during the active movements for signs of rigid segments indicating hypomobility or excessively mobile segments indicating hypermobility The distance between the fingertips and floor when the patient leans forwards is measured.

If pelvic imbalance or a difference in leg length is suspected the patient is placed on two scales. Any difference in the load is measured and one or more plates are placed under the shorter leg in order to test whether balance can be restored.

To distinguish between true leg-shortening and pseudo-shortening due to rotation of the pelvis (i.e one half of the pelvis is rotated forwards or backwards in relation to the other half) additional tests are performed in the prone and supine positions (see below).

Sitting

The position of the spine is checked once again and tests are carried out to see whether any scoliosis due to leg shortening disappears and whether the patient can sit up straight or adopts a special posture due to pain The rotation of the upper half of the body with the pelvis fixed is also investigated The patient sits astride the treatment bench The rotation is tested actively, passively and against resistance The main factor investigated in the passive tests is whether the spine permits a slight additional elastic stretching in the extreme position. Pain in any rotational direction shows which movement should be avoided during the investigation, particularly in the lateral position

Prone

Kibler s test is the first test performed in this position A fold of skin on each side of the spinal process is "rolled up" the spine between the thumbs and index fingers. A positive finding (a distinct change in consistency of the skin, with or without pain) suggests engagement of the corresponding segment, dermatome, myotome, or sclerotome A springing test for control of the elasticity between the vertebrae is also performed The index and middle fingers are placed stepwise over the transverse process of each vertebra. With the other hand placed over the fingers, light pressure is applied in the ventral direction Positive Kibler's test findings such as a dermatome, myotome or sclerotome, will now be discernible A " normal " elasticity between the vertebrae in spite of pain is a stronger indication of a myotome if several pairs of vertebrae are engaged and the muscle itself feels hard A dermatome is more local and shows segmental extension Lack of elasticity between one or more lumbar vertebrae must be further investigated in the lateral position

Hyper or hypomobility in the iliosacral joints is investigated Manual pressure is applied distally over the sacrum in the ventrocranial direction and the two iliosacral joints are palpated alternately and compared Slight elasticity should normally be detectable between the edges of the joint surfaces. If hypomobility is present the [illegible]

[illegible] up as high as the other leg the findings are positive This is known as Mennell s test.

In hypermobility the elasticity in the joint is considerably increased and is often associated with pronounced pain

The above tests for hyper and hypomobility place great demands on the therapist's palpation sensitivity

Any tension in the piriform muscle or pain from the origin of the iliac muscle is palpated The psoas and rectus femoris muscles are investigated to see whether they are shortened or contracted due to pain

According to Janda, the function of the above muscles is mainly postural i.e. they react to incorrect movements by contracting. The elasticity of the muscles and [illegible] is tested in the prone and the supine positions [illegible]
iliosacral [illegible]
the leg [illegible]
elasticit[illegible]

Supine

A straight leg raising test (SLR) is done and if this causes lumbar pain a forced test is performed i e. the foot is dorsiflected passively and the patient flexes his neck actively A positive SLR between 0 and 30° in the hip joint with increased radiation of pain to the lumbar region and along the sciatic nerve below the knee when the joint is forced also indicates root engagement Pain behind the knee and in the back of the thigh, often bilaterally, during passive leg lift above 45° indicates pseudo-positive SLR due to shortening of the hamstrings.

According to Janda, these muscles — biceps femoris, semimembranosus and semitendinosus — also belong to the group with mainly postural function If the patient is able to flex the hip joint to 80° with his leg straight the elasticity of the hamstrings is normal

For investigation of the hip joint, maximal flexion with the knee bent is checked and inward and outward rotation and adduction (Downing's test) are tested at 90° flexion

In Patrick's test for abduction the leg is allowed to fall outwards with the knee flexed and the foot level with the knee of the other leg, with fixation of the superior anterior iliac spine on the opposite side to prevent movement of the pelvis In all these tests the two sides are compared Positive findings in Patrick's and Downing's tests, i e reduced mobility often combined with pain, suggests blockage in the iliosacral joint if the findings for the hip joint in other tests are normal

Positive findings in Patrick's test may also be caused by contraction of the short adductors (mainly postural function) In this case the mobility will be fairly equal in the two hip joints during abduction and the patient will experience tightness in these groups of muscles

The ligamentous apparatus of the pelvis is also tested, particularly the iliolumbar, dorsal, iliosacral and sacrotuberal ligaments

In this test the ligament is first exposed to passive stretching With the patient in the supine position, the test leg is adducted at the hip with the knee flexed The degree of flexion and adduction in the hip joint depends on which ligament is to be tested The ligament is stretched by applying pressure to the adducted leg in the longitudinal direction of the femur for about 20 seconds An increased dull pain over the ilio sacral joint or in the groin may be a positive finding

Leg length is investigated once again if earlier tests of the pelvis indicated hypomobility with or without rotation To confirm this the following test is performed If the pelvis is "rotated", the legs become longitudinally displaced, relative to one another, when the patient sits up from the supine position with his legs straight The medial malleoli are used as reference-points. In a positive test one leg is displaced relative to the other and primary restriction of mobility is then almost always present in the pelvis and not in the lumbar spine This is known as the Yo-Yo test

Any radiation of the pain and abnormal sensibility is noted The strength of the rectus abdominis and obliquus muscles is checked and the iliopsoas muscle is investigated for contraction If the test in the prone position gave reason to suspect contraction, the following test is performed The patient sits on the edge of the treatment bench, lifts one leg and holds it flexed against his chest in order to fix his pelvis The patient is then helped into the supine position The leg being tested hangs

freely and relaxed If the psoas muscle is normal the thigh will hang below the horizontal line, and if the rectus femoris muscle is normal the knee can be flexed to 90° without causing flexion of the hip joint (to compensate for knee flexion)

Lateral position

With the patient in the lateral position, the specific mobility between the spinal processes is investigated A palpating finger is placed stepwise between two spinal processes and the patient s flexed leg is held with the other hand By lordosing and kyphosing the patient s lumbar spine alternately it should be possible to feel the spinal processes moving apart and towards each other A positive finding between two processes means too much (hypermobility) or too little (hypomobility) movement between the spinal processes compared to the movements in other segments.

It will often be found that the segment above or below a hypomobile segment is hypermobile Conversely, the segment above or below a hypermobile segment is often hypomobile

[illegible]

tween the spinal processes. Finally, the patient s pelvis and leg are held still and his spinal processes are palpated while he is made to perform rotational movements with his trunk All these tests are carried out in the least painful direction as indicated by findings in the standing or seated position

In general, the investigation in the lateral position is performed with the patient lying on the painful side Thus if the pain radiates down into the left leg, the patient lies on his left side

The findings of the investigation are assessed and the patient's treatment is individualized on the basis of these findings

Treatment

Patients with pronounced pain, sometimes in connection with postural scoliosis and difficulty in walking, have been taught how to lessen the strain on their back. When the pain begins to decline the patient returns for more specific tests and is treated in accordance with the findings.

Patients with restricted mobility are given mobilizing treatment for the hypomobile area Mobilization preferably means that only the hypomobile segment is moved passively (articulated), the adjacent mobile segments being fixed This is usually done with the patient in the lateral position when the lumbar spine is engaged

Patients with hypermobile segments are given stabilization exercises and [illegible] k
regimen described below [illegible]
of a chair how to sit pro [illegible]
exercises consist of the t [illegible]
the patient responding b [illegible]
with the individual segme [illegible]
the whole of the lumbar spine is stabilized [illegible] number of segments until

The aim of this treatment is to train the patient to stabilize certain parts of his back reflexively with his muscles and thus prevent the hypermobile parts from coming in to the extreme position and causing pain The patient is taught to work from his hip joints

Patients with a blocked iliosacral joint are treated with gapping The patient lies on the side in which the iliosacral joint is blocked (e g the left side) His left ilium is then fixed and his right leg is flexed at the hip joint The therapist holds the sacrum and right ilium fixed with one or both hands and places her finger tips just medial to the left iliosacral joint The patient performs a maximal right rotation of his trunk and body and tries to look at the floor while taking a deep breath and slowly breath ing out through his mouth Gapping occurs at the movement of relaxation caused by exhalation The effect can be checked immediately by repeating the passive leg lift test with the patient in the prone position If both legs are equally heavy and exten sion is increased the procedure has been successful

Patients with a rotated' pelvis are treated with articulation In cases in which the left ilium is rotated forwards (it is actually the sacrum that has rotated around its own axis) the patient is placed on his right side with his right leg fixed in extreme extension in order to lock the right ilium with the iliofemoral ligament The left hip joint is flexed and the therapist presses backwards on the superior anterior iliac spine with one hand and pulls on the ischial tuberosity with the other This results in a rotational movement in the left iliosacral joint A positive effect can immediately be detected by performing the Yo Yo test both legs now have the same length both when the patient is lying down and when he sits up Restitution of the balance can also be checked by placing the patient on two scales

Patients with contraction of postural muscles are given stretching exercises for the groups of muscles concerned For stretching of for example the hamstring muscles of the right leg the patient is placed in the supine position and his right hip joint is flexed until tightness occurs in the back of the knee and/or until the pelvis begins to rotate The patient is then made to perform a maximal isometric contraction of the hamstring muscles for 5 – 6 seconds against manual resistance This is followed by total relaxation during which the leg is immediately flexed passively at the hip joint with the pelvis firmly fixed and the leg straight It is important to avoid the slightest abduction adduction or rotation in the hip joint The leg is held in this new position for up to 20 seconds The exercise is repeated 4 – 5 times each time in the new starting position that the increased elasticity of the hamstring muscles allows The passive stretching occurs during the muscle s refractory period

These exercises which the patient also performs at home using a somewhat differ ent technique but according to the same basic principles must not be carried out in the morning Through this special stretching technique several of the normal pro tective mechanisms of the muscle are put out of action Fine coordination through the gamma system does not function satisfactorily until some hours after the indi vidual gets up

Patients with weak muscles are of course given static and dynamic exercises to in crease their strength

72 patients were allocated at random to the above described treatment Four patients never came to treatment The non treated patients were included in the physiotherapy group in all analyses except the estimation of the duration of symptoms following the first treatment.

The number of treatments in the physiotherapy group were maximized to ten The average number of treatments given were four

Table 7 shows the clinical findings and subsequent treatment of 68 pa tients assessed by the physiotherapists

"Placebo"

Short waves of the lowest possible intensity has been the third method of treating a group of patients The heat produced at this intensity may, at the most increase the local blood flow of the subcutaneous tissues (Hovind & Nielsen 1973)

This treatment has therefore been regarded as a placebo

75 patients in this study were randomized to this third group 59 patients followed the treatment

A maximum of ten treatments was given to each patient The average number of treatments given were five

The non treated patients were included in the "placebo" group in all analyses except the estimation of the duration of symptoms following the first treatment

Table 7 Distribution of clinical findings and subsequent treatment in the physical therapy group – The therapists' assessment

Diagnosis	No	%	Treatment[1]
Hypomobile lumbar segment	11	16	1 Articulation of hypomobile segment with simultaneous fixation of adjacent segments 2 Specific movement promoting active exercises of the engaged segments
Hypomobile lumbar segments and shortened postural muscles	6	9	1 Articulation 2 Specific movement promoting active exercises 3 Stretching of shortened postural muscles
Hypomobile sacro-iliac joint	8	12	1 Gapping with blockade 2 Articulation with rotated pelvis
Hypomobile sacro-iliac joint and shortened postural muscles	4	6	1 Gapping or articulation 2. Stretching of shortened postural muscles
Hypomobile lumbar segment and hypomobile sacro iliac joint	9	13	1 Articulation of hypomobile lumbar segment 2 Gapping or articulation of hypomobile sacro-iliac joint 3 Specific movement promoting active exercises
Hypomobile lumbar segment hypomobile sacro iliac joint and shortened postural muscles	4	6	1 Articulation of hypomobile lumbar segment 2 Gapping or articulation of hypomobile sacro-iliac joint 3 Stretching of shortened postural muscles 4 Specific movement promoting active exercises
Disc engagement	8	12	1 Pain relief a) analgesics b) unloading resting position usually Semi-Fowler position 2 Test traction
Muscular disorders	15	22	According to clinical findings one or a combination of the following alternatives 1 Heat 2 Stretching of shortened postural muscles 3 Isometrical strengthening-exercises of weak muscles 4 Exercises of endurance 5 Exercises of coordination 6 General physical exercises
Inflammation of the dura mater	3	4	Antiphlogistics

[1] The methods of treatment are mentioned in the same order as they are performed on the patients

Stratification and randomization

Stratification of the patients was based on vocational and psychologic factors The vocational and psychologic forms described on pages 23 27 were filled in by the patient at the screening assessment and given a score according to a standardized pattern The vocational questionnaire scored from 10 – 30 points The hs and hy scales had scores from 0 – 41 points and 0 – 31 points respectively

Every score above or below a middle value of each scale was given a code

Depending on the scores of the questionnaires each patient was at last provided with one of eight possible combinations of codes. The eight combinations of codes were used when randomizing the patients to one of three modes of therapy Separate tables of random numbers were used for each combined code

Evaluation of results

When estimating the relation between certain confounding factors and certain criterion variables the data was arranged in the form of contingency tables from which chi-square test was carried out The median values of the criterion variables were used in the contingency tables for the calculations with chi square test. The median values were chosen due to a skew distribution of the criterion variables

Contingency tables and chi square test were also used when comparing absence from work number and length of recurrences in one year in the three groups of therapy

When estimating the differences in "pain index between the treatment groups an analysis of variance was performed and contrasts of the differ ences between the three groups were constructed

A covariance analysis was used when comparing the duration of symptoms following the first treatment in the three groups. The covariance analysis was used to see whether possible effects of any of the treatments could be explained by differences in time between the onset of symptoms to the first treatment in the treatment groups.

The test functions of covariance analysis require underlying normal dis tributions and as the distribution of the duration of the initial episode was rather skew logarithms of the values were used.

Results Part I

The profile and the clinical manifestations in the 217 patients are presented in Part I, by means of frequency tables

Results Part II

The influence of certain confounding factors on the course of acute and subacute low back pain is assessed by relating the confounding variables to

1 The duration of the initial episode,

2 the duration of sick-leave during the initial episode,

3 the summarized duration of recurrences of pain in one year, and

4 the total absence from work in one year owing to recurrences

Results Part III

The efficacy of the three different modes of treatment for acute and sub acute low back pain is evaluated by comparing

1 The duration of symptoms following the first treatment,

2 the length of absence from work during the initial episode

3 the variation in experience of pain during the initial episode by means of the "pain index" (see Methods page 28)

4 the number of recurrences in one year,

5 the length of recurrences in one year, and

6 the total absence from work in one year owing to recurrences

RESULTS PART I

PATIENT PROFILE

Age and sex

The distribution by age and sex in the studied population is illustrated in Fig 1 13 % of the patients in the study were women while 20 % of the employees at Volvo Gothenburg are women

The youngest patient in this study was 17 years old and the oldest was 64 years of age The median age was 34 5 years

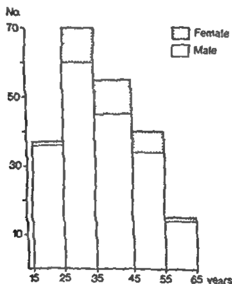

Fig 1 Age and sex distribution of the patients.

History of back pain

43 % of the patients reported no previous episodes of back pain 32 % had had back pain only once before, while 25 % of the patients had had more than one episode of back pain Table 8

Results Part I

The profile and the clinical manifestations in the 217 patients are presented in Part I, by means of frequency tables

Results Part II

The influence of certain confounding factors on the course of acute and subacute low back pain is assessed by relating the confounding variables to

1 The duration of the initial episode,
2 the duration of sick leave during the initial episode,
3 the summarized duration of recurrences of pain in one year, and
4 the total absence from work in one year owing to recurrences

Results Part III

The efficacy of the three different modes of treatment for acute and sub acute low back pain is evaluated by comparing

1 The duration of symptoms following the first treatment,
2 the length of absence from work during the initial episode,
3 the variation in experience of pain during the initial episode by means of the "pain index" (see Methods, page 28)
4 the number of recurrences in one year,
5 the length of recurrences in one year, and
6 the total absence from work in one year owing to recurrences

Duration of symptoms before entry to the study

The time between the onset of back pain and the initial assessment of the patient ranged from 1 to 86 days Most patients (83 %) had had their back pain for less than three weeks at the first examination The median duration of symptoms of the studied group before entry to the study was 9 days The duration of symptoms before entry to the study is shown in Table 10

Table 10 Duration of symptoms before entry to the study

Duration of symptoms	Number of patients
Less than 1 week	79
1 to 2 weeks	63
2 to 3 weeks	37
3 to 4 weeks	11
4 to 8 weeks	25
More than 8 weeks	2

Subjective symptoms

The pain was considered intensive by 67 % and not intensive by 33 % of the patients, according to the ten possible answers to the questions regarding pain Continuous pain during the day was reported by 49 % while the remaining patients stated that pain occurred only in connection with movements or strain Some pain at night was experienced by 40 %, but only 23 % of all the patients reported sleep disturbances The pain was accentuated by coughing and sneezing in 42 % of the patients The characteristics of pain in the group of patients are presented in Table 11

Table 8 The occurrence of previous episodes of back pain.

Number of episodes	Number of patients
None	93
One	69
Two	15
Three	10
More than three	27
Information lacking	3

Onset of current episode of back pain

The onset of back pain was sudden in 44 % of the group while 56 % of the patients reported a more insidious onset 42 % stated that the symptoms had started during working-hours and 51 % of the patients reported that the pain first occurred during leisure time 7 % were unable to relate the onset of their symptoms to time In 45 % of the patients the symptoms appeared in connection with a specific incident i e bending, twisting, lifting, a sudden movement or a fall The circumstances of the onset of symptoms are shown in Table 9

Table 9 Circumstances of the onset of back pain.

		Number of patients
Type of onset	sudden	96
	insidious	121
Time of onset	working hours	92
	leisure time	110
	uncertain	15
Incident related to onset	none	119
	a fall	2
	a lift	36
	bending	34
	a sudden movement	7
	other incident	17
	information lacking	2

Location of pain

All the patients had pain in the lumbar region The pain was mainly located centrally in the lower lumbar area or in the paravertebral region as illustrated in Fig. 2 Pain in the gluteal region or the thigh occurred in 26 % of the patients Pain was more common in the right gluteal region and thigh than on the left side

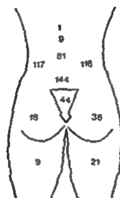

Fig 2 Location of pain in the studied patients. Combination of the locations of pain is possible Figures = number of patients.

Objective findings

The Straight Leg Raising test (SLR) was performed The test was positive unilaterally in 27 % and bilaterally in 35 % of the patients Only 14 % of the patients had an SLR below 60°

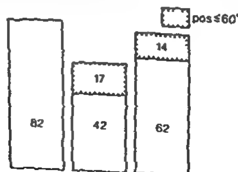

Fig 3 The straight leg raising test

Table 11. Characteristics of pain

	Number of patients			
	Yes	No	Uncertain	Total
Intensive pain	145	72	0	217

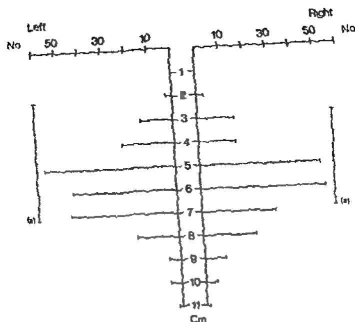

Fig 5 The range of lateral flexion (a) = mean values of lateral flexions + 2 s d in a normal population of 35-year-old males

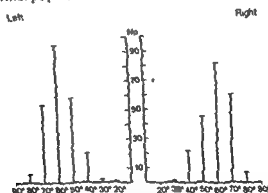

Fig 6 The range of rotation

The presence of postural scoliosis, paravertebral muscle spasm, and tenderness on palpation and percussion was registered Less than 20 % of the patients had pronounced paravertebral muscle spasm and postural scoliosis

Tenderness on palpation was registered in 60 % and tenderness on percussion in 39 %.

Impaired and fixed gait was present in 9 % of the patients.

The range of flexion, extension, and lateral flexion, measured by a modification of Schober's method, and the range of rotation are presented in Figs 4 – 6. Values for a normal population of 35-year-old males are inserted in the figures These values were taken from a study by Moll and Wright (1971) who used the same method A decreased ability to bend forwards was observed in the studied group of back patients compared with the values of the normal population The range of extension and lateral flexion did not differ from the values obtained in the normal population

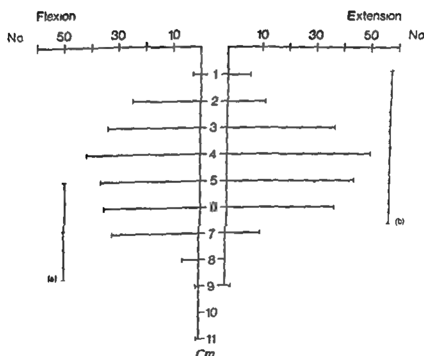

Fig 4. The range of flexion and extension. (a) = mean value of flexion ± 2 s.d in a normal population of 35-year-old males (b) = mean value of extension ± 2 s d in a normal population of 35-year-old males

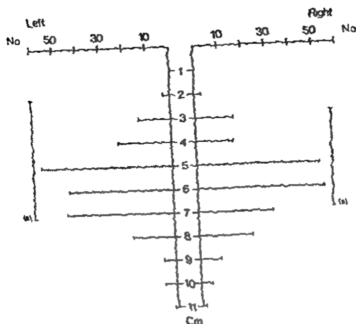

Fig 5 The range of lateral flexion (a) = mean values of lateral flexions ± 2 s d in a normal population of 35 year-old males

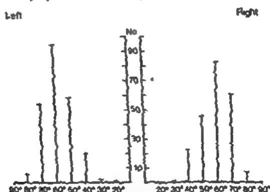

Fig 6 The range of rotation

The presence of postural scoliosis, paravertebral muscle spasm, and tenderness on palpation and percussion was registered Less than 20 % of the patients had pronounced paravertebral muscle spasm and postural scoliosis.

Tenderness on palpation was registered in 60 % and tenderness on percussion in 39 %

Impaired and fixed gait was present in 9 % of the patients.

Pain was registered in the planes of motion as well as when doing sit-ups and back-lifts An increase of pain when bending forwards was reported by 89 % of the patients while increase of pain was not so frequent in the other planes of motion The additional clinical findings are presented in Table 13

Table 13 Additional clinical findings.

Clinical findings		Number of patients Yes	No
Postural scoliosis		40	177
Muscle spasm		38	179

Reduced ability to do sit ups		185	32
Reduced ability to do back lifts		101	116

Vocational factors

Of the 217 patients 59 were office staff and 158 were manual workers This proportion corresponds well to the proportion of office staff and manual workers at Volvo, Goteborg Fig 7

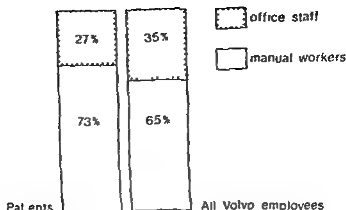

Fig 7 The proportions of office staff and manual workers among 217 patients in relation to the proportions of all employees at Volvo

Of the manual workers 71 were working according to a two-shift schedule while the remaining patients were working a day time schedule The proportions of shift workers and day time workers are compared with the corresponding proportions among all employees at Volvo Göteborg in Fig 8

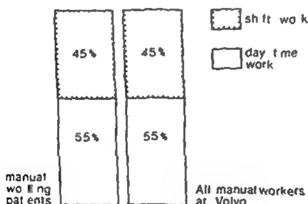

Fig 8 The proportion of daytime and shift workers among the patients in relation to the corresponding proportions at Volvo

The patients assessment of the postures required in their work is shown in Table 14 A predominance of the standing posture for the greater part of the day was reported by the manual workers A fixed posture throughout the working day was reported by 26 % of the patients.

Table 14 Patients' answer regarding their working postures Manual workers = m, Office staff = o

Working posture	Often No	% m, o	Sometimes No	% m, o	Rarely No	% m, o
Sitting*	55	(13, 60)	34	(15,17)	127	(72,23)
Standing	135	(77, 23)	39	(14, 26)	43	(9, 51)
Fixed working posture	Fixed		Partly fixed		Varied	
	52	(26, 16)	69	(38, 12)	96	(36, 72)

* Data lacking for one patient

The necessity for bending, twisting, lifting and forceful movements, according to the patients, is presented in Table 15 A high frequency of bending and twisting movements was reported by the manual workers while lifting and forceful movements were not considered to be necessary as frequently

Table 15 Patients' answers regarding movements required during work. Manual workers = m, Office staff = o

Type of movement	Often No	% m, o	Sometimes No	% m, o	Seldom No	% m, o
Bending forward	140	(81, 19)	34	(14, 21)	43	(5, 60)
Twisting	140	(79, 21)	37	(16, 21)	40	(5, 58)
Lifting (⩾ 5 kg)	66	(39, 5)	62	(36, 9)	89	(25, 86)
Lifting (⩾ 20 kg)	25	(14, 2)	37	(23, 4)	155	(63, 94)
Forceful movements	25	(15, 2)	38	(24, 0)	154	(61, 98)

Table 16 illustrates the need to concentrate during work, the degree of variation in working tasks and the possibilities of taking pauses during work A high proportion of the patients reported a moderate to great need to concentrate during the working day Variation in working tasks was more frequent than no variation Manual workers predominate among patients giving answers representing no necessity for concentration, no variation and no possibility to take pauses during work

Table 16 Variation, pauses and need to concentrate during work, Manual workers = m, Office staff = o

	Often No	% m, o	Sometimes No	% m, o	Seldom No	% m, o
Concentration necessary	96	(41, 51)	87	(38, 47)	34	(21, 2)

Relations with colleagues	194	(90, 89)	21	(9, 11)	2	(1, 0)

The tendency to report sick under any diagnosis during two years before entry to the study was registered for the 217 patients The mean duration of sick-leave was 15 5 days per year The distribution of sick-listing during these two years is shown in Fig. 10

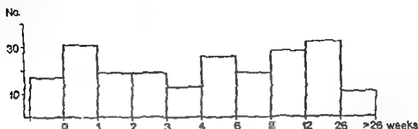

Fig 10 Sick-listing of all patients during two years before entry to the study

Psychological factors

The scores of the Hy and Hs-scales of the MMPI test are illustrated in Fig. 11 There is a pronounced accumulation around the lowest values of the Hy scale A normal distribution of the Hs-scale was observed, although with some shift towards lower values.

Fig 11 Scores of Hs- and Hy scales expressed in per cent of the maximal values The range of scores is 0 – 41 points for the Hs scale and 0 – 31 points for the Hy-scale.

Regular participation in physical exercise was reported by 34 % of the patients and 16 % were actively engaged in some kind of sport.

The previous or recent occurrence of psychosomatic symptoms is given in Table 20.

Table 20 Psychosomatic symptoms.

Symptoms	Number of patients		
	Yes	No	
Gastric or duodenal ulcer	13	204	
Frequent headaches	12	205	
	Recently	Previously	No
Gastritis, irritable colon	17	65	135
	Often	Sometimes	Never
Palpitations or dis comfort in the chest	8	22	187

It was found that 12 % of the patients had had continuous contacts with the social welfare authorities since the start of the investigation in 1974 The reasons for these contacts are presented in Table 21.

Table 21 Contact with social welfare authorities.

Reason for contact	Number of patients
Constant financial problems	22
Family problems	8
Difficulties in adjusting	12
Alcoholic problems	7

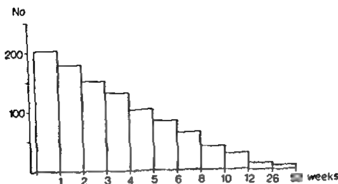

Fig 13 Duration of the initial episode of pain

Duration of sick leave during the initial episode

During the initial episode 34 patients were never sick-listed The sick-listing of the other 184 patients is presented in Fig 14 68 % of the sick-listed patients were back at work within one month. The median duration of sick leave when it occurred, was 21 days.

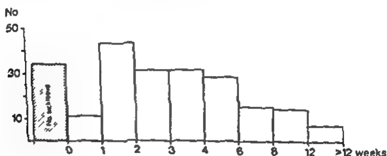

Fig 14 Duration of sick leave during the initial episode

Changes in clinical manifestations during the initial episode

The location of pain

The location of pain at the initial examination and at ten days, three weeks and six weeks is given in Table 22

The scores on the scales of extroversion (E), and neuroticism (N) of the Eysenck test are shown in Fig 12 The range of scores for both scales is 0 – 24 points The median score was 12 for the (E) scale and 5 for the (N) scale The lie-scale, ranging from 0 – 9 points, with a median score of 3 5 points, was normally distributed

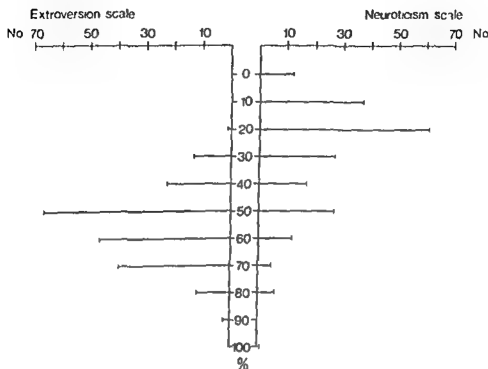

Fig 12 Scores on the extroversion and neuroticism scales of the Eysenck test expressed in per cent of the maximal score The range of scores for both scales is 0 – 24 points

COURSE OF THE DISEASE DURING ONE YEAR

Duration of the initial episode of pain

The time from the onset of pain until the disappearance of symptoms is presented in Fig 13 None of the patients had a duration of symptoms shorter than one week The pain disappeared within one month in 35 %, within two months in 70 % and within three months in 86 % of the patients An initial episode of pain lasting more than six months was found in six per cent of the patients, while four per cent still experienced pain after one year The median duration of pain was 35 days

The location of pain at the different assessments was uniform At the six-week assessment there was a tendency towards an increased radiation of pain to the thighs

"Pain index"

The change of pain during the first six weeks after the initial assessment as determined by means of the "pain index" is shown in Table 23 and Fig 16 There was a marked decrease of the pain index score between the initial and the 10-day assessment, indicating relief of pain during this period. At the three-week examination the median value of the pain index was unchanged, while it was slightly raised among those who still had pain at the six week examination

Table 23 The change of pain during six weeks expressed as median values of the pain index scores. The range of scores of the pain index is 0 – 70 points.

	Time of examination Initial	10 days	3 weeks	6 weeks
Median value	42	22	22	27
Number of patients	217	151	86	45

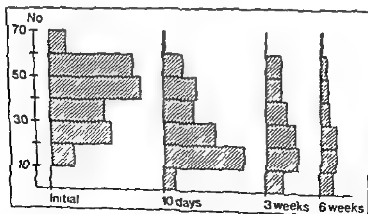

Fig 16 The change of pain during six weeks as determined by means of the "pain index" The range of scores of the "pain index" is 0 – 70 points

Table 22 Location of pain during the first six weeks of the initial episode

Location of pain		Time of examination Initial %	10 days %	3 weeks %	6 weeks %
Central pain	A	5	4	3	4
	B	37	38	34	47
	C	66	71	67	80

Thigh pain	I	4	7	6	11
	J	10	6	9	13
No of patients		217	151	86	55

The zones for the location of pain are shown in Fig. 15

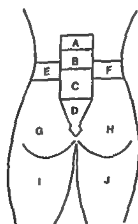

Fig 15 Zones for the location of pain

Total duration of recurrences of pain in one year

The total duration of all recurrences of pain during one year of observation for the 134 patients with relapses is presented in Fig 17 The duration of all recurrences varied from less than one week to 40 weeks The median duration of all recurrences was 27 days.

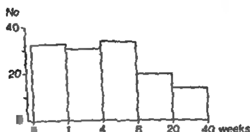

Fig 17 Total duration of recurrences of pain in one year (n = 134 patients

Total duration of absence from work in one year owing to recurrences

Among all the patients with recurrences of pain 66 patients were never absent from work The duration of sick leave during the recurrences varied from less than one week to 30 weeks, Table 26 The median duration of sick leave during all the recurrences was 16 days

Table 26 Total duration of sick leave during all recurrences. n = 68 patients.

Time (weeks)	0–1	1–2	2–4	4–8	8–30
Number of patients	7	23	17	14	7

Recurrences of pain in one year

Number of recurrences of pain

During the year of observation 62 % had one or more recurrences of pain More than six recurrences were not observed in any of the patients. The distribution of recurrences is illustrated in Table 24 The median number of recurrences was 1 3

Number of patients	8	22	16	26	31	31

RESULTS PART II

INFLUENCE OF CONFOUNDING FACTORS ON THE COURSE OF THE DISEASE

The factors characterizing the patient profile (part I) were related to 1) the duration of symptoms during the initial episode of pain, 2) the duration of sick-leave during the initial episode, 3) the total length of recurrences of pain in one year and 4) the total duration of absence from work due to recurrences in one year

History of back pain

Earlier episodes of back pain

The course of the disease was found not to differ between patients with earlier low back disorders and those who reported no earlier episodes of back pain

Onset of symptoms

A tendency ($p < 0.05$) towards a longer duration of the initial episode was found among patients with an insidious onset compared to those with a sudden onset of pain The course of the disease was not influenced by the type of onset of symptoms in any other way.

Clinical findings

"Pain index"

The "pain index", based on the sum of scores of several questions regarding the duration of pain, ranged from zero to 70 points

Total duration of low back pain in one year

The duration of episodes of low back pain during one year of observation was calculated The duration of back pain in one year among 217 patients is given in Fig 18 During the time of the study 24 % of the patients had back pain for less than one month, 47 % had back pain for less than two months, 66 % for less than three months and 88 % for less than six months The median duration during one year was 60 days

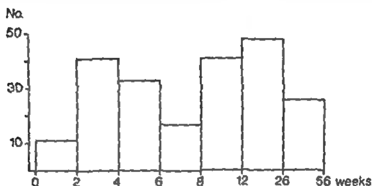

Fig 18 Total duration of low back pain in one year

Development of rhizopathy

During the time of the study 8 % of the patients developed sciatica resembling rhizopathy, with or without neurological findings. No surgery for disc herniation was carried out.

Development of lumbar insufficiency

In addition to the registered episodes of low back pain 62 % of the patients had one or more episodes of lumbar insufficiency i e fatigue and discomfort in the back during strenuous movements

Change of occupation

During this study of 217 patients with acute low back pain 52 % changed their jobs The back disorders were reported to be the main reason for changing jobs by 32 % of these patients The transfer took place within Volvo or to another company

RESULTS PART II

INFLUENCE OF CONFOUNDING FACTORS ON THE COURSE OF THE DISEASE

The factors characterizing the patient profile (part I) were related to 1) the duration of symptoms during the initial episode of pain, 2) the duration of sick leave during the initial episode, 3) the total length of recurrences of pain in one year and 4) the total duration of absence from work due to recurrences in one year

History of back pain

Earlier episodes of back pain

The course of the disease was found not to differ between patients with earlier low back disorders and those who reported no earlier episodes of back pain

Onset of symptoms

A tendency ($p < 0.05$) towards a longer duration of the initial episode was found among patients with an insidious onset compared to those with a sudden onset of pain The course of the disease was not influenced by the type of onset of symptoms in any other way

Clinical findings

"Pain index"

The "pain index", based on the sum of scores of several questions regarding the duration of pain, ranged from zero to 70 points

The patients whose scores were above the median value for the initial examination were found to have a longer absence from work ($p < 0.05$) during the initial episode than the patients with less pronounced pain, according to the index A high pain score at the initial assessment was found not to prolong the initial episode However, a much longer initial episode of pain ($p < 0.001$), with a subsequent longer absence from work ($p < 0.001$), was found among patients still afflicted with severe pain at the ten-day examination, compared to patients with only moderate pain

The "pain index" score at the ten-day examination was not related to the length of relapses or absence from work in connection with relapses

Objective findings

No evidence was found of a relation between the course of back pain during the year of observation and the range of motions (flexion, extension, lateral flexion and rotation) registered at the initial assessment The presence of clinical manifestations, like postural scoliosis and radiation of pain in one or both thighs, did not seem to influence the course of the ailment

The duration of sick leave during the initial episode was found to be significantly longer ($p < 0.01$) among patients who manifested pain on percussion of the lower lumbar spine The duration of absence from work during the initial episode was also significantly longer ($p < 0.01$) among patients who had a positive Straight Leg Raising Test (SLR) at the initial assessment

There were no indications of a relation between the presence of pain on percussion and SLR and the remaining variables determining the course of acute back pain

Vocational factors

Mechanical strain and working postures

The influence of working postures on the duration of the initial episode was observed among patients who sat less than two hours per day ($p < 0.05$), bent ($p < 0.01$) and twisted ($p < 0.05$) their backs more than ten

times per hour and who were forced into fixed postures ($p < 0.05$) for the greater part of the working day. Correspondingly shorter durations were found among patients who sat more than four hours a day, who seldom bent or twisted their backs and whose postures varied. No relation was found between a longer duration of the initial episode and standing, lifting and forceful movements.

Patients whose work involved sitting for less than two hours per day ($p < 0.001$), frequent bending ($p < 0.001$) and twisting ($p < 0.01$) movements and lifting (≥ 5 kg) at least ten times per hour ($p < 0.01$) were absent from work longer during the initial episode. No relation was found between longer sick leave and fixed postures, standing, lifting (≥ 20 kg) and forceful movements.

Fixed working postures were found to be related to a longer duration of symptoms due to relapses in one year ($p < 0.01$).

None of the other working postures tested showed any relation to the duration of recurrences.

A longer duration of sick-leave during relapses was related to bending ($p < 0.05$) and twisting ($p < 0.01$) more than ten times per hour as well as frequent forceful movements ($p < 0.05$).

The amount of sitting, standing, fixed postures and lifting was not related to the length of absence from work during relapses.

Vocational exhaustion

A significantly longer duration of the initial episode was observed among patients who experienced daily *fatique in their backs* ($p < 0.01$) before the present episode and among patients who were exhausted after work ($p < 0.05$).

No evidence was found of a relation between fatigue and absence from work or recurrences. Only the patients who reported daily nervousness after work exhibited a longer total duration of relapses ($p < 0.01$) in a year.

The patients whose scores were above the median value for the initial examination were found to have a longer absence from work ($p < 0.05$) during the initial episode than the patients with less pronounced pain, according to the index. A high pain score at the initial assessment was found not to prolong the initial episode. However, a much longer initial episode of pain ($p < 0.001$), with a subsequent longer absence from work ($p < 0.001$), was found among patients still afflicted with severe pain at the ten-day examination, compared to patients with only moderate pain

The "pain index" score at the ten day examination was not related to the length of relapses or absence from work in connection with relapses

Objective findings

No evidence was found of a relation between the course of back pain during the year of observation and the range of motions (flexion, extension, lateral flexion and rotation) registered at the initial assessment The presence of clinical manifestations, like postural scoliosis and radiation of pain in one or both thighs, did not seem to influence the course of the ailment

The duration of sick leave during the initial episode was found to be significantly longer ($p < 0.01$) among patients who manifested pain on percussion of the lower lumbar spine The duration of absence from work during the initial episode was also significantly longer ($p < 0.01$) among patients who had a positive Straight Leg Raising Test (SLR) at the initial assessment

There were no indications of a relation between the presence of pain on percussion and SLR and the remaining variables determining the course of acute back pain

Vocational factors

Mechanical strain and working postures

The influence of working postures on the duration of the initial episode was observed among patients who sat less than two hours per day ($p < 0.05$), bent ($p < 0.01$) and twisted ($p < 0.05$) their backs more than ten

times per hour and who were forced into fixed postures ($p < 0.05$) for the greater part of the working day Correspondingly shorter durations were found among patients who sat more than four hours a day, who seldom bent or twisted their backs and whose postures varied No relation was found between a longer duration of the initial episode and standing, lifting and forceful movements

Patients whose work involved sitting for less than two hours per day ($p < 0.001$) frequent bending ($p < 0.001$) and twisting ($p < 0.01$) movements and lifting (≥ 5 kg) at least ten times per hour ($p < 0.01$) were absent from work longer during the initial episode No relation was found between longer sick leave and fixed postures standing lifting (≥ 20 kg) and forceful movements

Fixed working postures were found to be related to a longer duration of symptoms due to relapses in one year ($p < 0.01$)

None of the other working postures tested showed any relation to the duration of recurrences

A longer duration of sick leave during relapses was related to bending ($p < 0.05$) and twisting ($p < 0.01$) more than ten times per hour as well as frequent forceful movements ($p < 0.05$)

The amount of sitting standing fixed postures and lifting was not related to the length of absence from work during relapses

Vocational exhaustion

A significantly longer duration of the initial episode was observed among patients who experienced daily fatique in *their backs* ($p < 0.01$) before the present episode and among patients who were exhausted after work ($p < 0.05$)

No evidence was found of a relation between fatigue and absence from work or recurrences. Only the patients who reported daily nervousness after work exhibited a longer total duration of relapses ($p < 0.01$) in a year

Variation concentration and breaks at work

A longer duration of the initial episode together with a longer duration of absence from work was registered among patients with repetitive ($p < 0.001$, $p < 0.05$) or monotonous ($p < 0.01$) jobs compared to patients with varied jobs Low requirements of concentration at work were also related to a longer duration of sick leave during the initial episode ($p < 0.05$)

The number of breaks during the working day did not seem to influence the course of the disease

Job satisfaction

Patients reporting discontent with their jobs were found to have a longer initial episode ($p < 0.01$) and a longer absence from work ($p < 0.05$) than the satisfied patients

Dissatisfaction with the working environment was also associated with a longer duration of absence both during the initial episode ($p < 0.001$) and during recurrences ($p < 0.05$)

Relations with colleagues and a desire to change jobs did not have any significant influence on the course of the disease

Category of employment

The course of the disease was compared between office staff and manual workers because of the different working conditions in the two groups

A significantly longer initial episode ($p < 0.01$) a longer duration of absence during the initial episode ($p < 0.001$) and an increased duration of sick leave during relapses ($p < 0.01$) were observed among the manual workers with correspondingly shorter durations among the office staff

There was no relation between the category of employment and the duration of recurrences

Influence of vocational factors on the course of the disease among manual workers and office staff separately

A separate analysis of the influence of vocational factors was carried out on each category of employees because of the significant differences in the two groups regarding the duration of the initial episode and absence from work The same vocational variables were tested as on the whole population

A significantly longer duration of the initial episode was still observed in manual workers who stated daily back fatigue ($p < 0.5$) and who had repetitive ($p < 0.01$) and monotonous ($p < 0.05$) jobs A longer absence from work during the initial episode was also observed in manual workers who sat less than two hours per day ($p < 0.05$) compared to the manual workers who sat for much of their working day or needed to bend only occasionally

None of the other vocational factors had an influence on the course of the disease when related to each category alone, provided that the significance test could be carried out

The influence of most of the vocational factors could not be assessed among office staff separately as the distributions in the alternative answers to the questions asked, were highly skewed

Skew distributions were also found among the manual workers in respect of the questions concerning the amount of bending and twisting. Only very few workers were not required to bend and twist frequently at work and the chi-square test could therefore not be applied Similarly, it was not possible to evaluate the influence of job satisfaction since the number of manual workers who were discontented with their work was insufficient to be related to the course determining variables

Interrelations between vocational factors

Working postures

Highly significant relations were obtained between standing for more than four hours per day and sitting for less than two hours per day and frequent bending twisting, lifting, forceful movements and fixed postures ($p < 0.001$)

Variation, concentration and breaks at work

A longer duration of the initial episode together with a longer duration of absence from work was registered among patients with repetitive ($p < 0.001$, $p < 0.05$) or monotonous ($p < 0.01$) jobs compared to patients with varied jobs. Low requirements of concentration at work were also related to a longer duration of sick-leave during the initial episode ($p < 0.05$).

The number of breaks during the working day did not seem to influence the course of the disease.

Job satisfaction

Patients, reporting discontent with their jobs were found to have a longer initial episode ($p < 0.01$) and a longer absence from work ($p < 0.05$) than the satisfied patients.

Dissatisfaction with the working environment was also associated with a longer duration of absence both during the initial episode ($p < 0.001$) and during recurrences ($p < 0.05$).

Relations with colleagues and a desire to change jobs did not have any significant influence on the course of the disease.

Category of employment

The course of the disease was compared between office staff and manual workers because of the different working conditions in the two groups.

A significantly longer initial episode ($p < 0.01$), a longer duration of absence during the initial episode ($p < 0.001$) and an increased duration of sick leave during relapses ($p < 0.01$) were observed among the manual workers with correspondingly shorter durations among the office staff.

There was no relation between the category of employment and the duration of recurrences.

Eysenck test

Extroversion and neuroticism

High and low scores on the scales of extroversion and neuroticism were compared and related to the course of pain and absence from work during the year of observation Patients having a low score on the scale of extroversion tended to have more days of pain due to relapses in the year of observation ($p < 0.05$) The other scores on the two scales were not found to be course related

Social factors

A significantly longer duration of pain ($p < 0.01$) during the initial episode was found among patients who had had continuous contact with the social welfare authorities since 1974, compared to the patients without any known contact with the social welfare authorities Neither the duration of sick leave nor the total duration of recurrences in one year was related to contact with the social welfare authorities

Previous psychosomatic symptoms

The course of low back pain was not related to affirmative answers to questions concerning previous psychosomatic symptoms

Tendency to report sick

Patients who, according to the NHIO, were sick listed under any diagnosis for long periods of time during the two years before entry to the study were also absent from work much longer during the initial episode of pain ($p < 0.001$) than patients with a shorter record of sick leave during the two years preceding the study The amount of sick-listing during these two years did not influence the sick listing during recurrences or the duration of episodes of back pain during the year of observation

Participation in physical exercise

Patients who regularly participated in physical exercise did not show any dissimilarity in the course of back pain compared to patients who only occasionally or never took exercise

Frequent bending, twisting, lifting, forceful movements and fixed postures were all found to be strongly correlated to one another ($p < 0.001$)

Vocational exhaustion

Daily back fatigue was significantly related to exhaustion after work ($p < 0.001$)

Variation and concentration

Highly significant relations were obtained between repetitive work, monotonous work and work involving little need for concentration ($p < 0.001$)

Job satisfaction

The patients who reported dissatisfaction with their jobs were also dissatisfied with their working environment ($p < 0.001$)

Interrelations between working postures, vocational exhaustion, variation and concentration, and job satisfaction

Significant relations were also obtained between demanding working postures, pronounced vocational exhaustion, little variation, low requirements of concentration and discontent with duties and the working environment

Psychological factors

The Hy- and Hs scales

The course of the initial episode was compared between patients given a score above and below the median value on the Hy-scale The patients with scores above the median value (2 points) were absent from work significantly longer during the initial episode ($p < 0.05$) No other differences in the course were observed between the two groups The patients who had scores above six points were than compared with the patients with zero points and a significantly longer duration of the initial episode of pain ($p < 0.05$) was found among the patients with scores above six points When the same procedure was carried out on the Hs-scale no differences were detected between patients with scores above and below the median value or between groups of patients with extreme scores

Demographic factors

Age

Patients below 30 years of age tended to have a significantly longer initial episode of pain ($p < 0.05$) and longer absence from work during relapses in the year of observation ($p < 0.05$) compared to the age groups 30 to 50 years and above 50 years of age. The other course-determining variables were not related to age.

Sex

No differences were observed between men and women as regards the duration of back pain and subsequent absence from work during one year.

Table 27 summarizes all the confounding factors found to be of significance in relation to the periods of pain and absence from work in one year.

RESULTS PART III

EFFECTS OF THERAPY

Duration of symptoms in the treatment groups following the first treatment

A comparison of the duration of symptoms following the first treatment between the treatment groups was performed. The influence of the time between onset of symptoms and first treatment (x) was eliminated by means of a covariance analysis with x as a concomitant variate. The adjusted mean values of the time between first treatment and recovery (y) were compared Fig. 19. The antilogarithms of the adjusted mean values were 14.8 days for the Back School group, 15 8 days for the combined physiotherapy, and 28 7 days for the "placebo" group. The 95 % confidence interval for the difference between the combined physiotherapy group and the "placebo" group was 0.59 ± 0.37. No difference was detected between the Back School group and the combined physiotherapy group

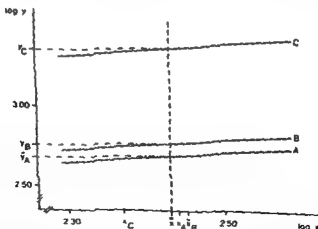

Fig. 19 The regression lines of the time between first treatment and recovery (y) on the time between onset of symptoms and first treatment (x) of the groups. Number of days in logarithms. $\bar{\bar{x}}$ = overall mean. A = Back School, B = Combined physiotherapy, C = "Placebo".

The change of pain during the initial episode

The change of pain and the degree of functional limitation in the treatment groups are shown in Table 29 and Fig. 20 in terms of the "pain index" as described on page 28

Table 29 The change of pain during six weeks in the treatment groups by means of the median values of the "pain index" Range of scores for the "pain index" = 0 – 70 points. Group A = Back School, Group B = Combined physiotherapy Group C = Placebo. Figures within parentheses indicate the number of patients examined on each occasion.

	Time of examination			
	Initial	10 days	3 weeks	6 weeks
Group A	43	20	19	22
	(70)	(44)	(25)	(14)
Group B	42	22	18	21
	(72)	(50)	(19)	(16)
Group C	42	28	25	17
	(74)	(56)	(32)	(15)

A similar decrease of pain was observed in all three groups from the initial to the six week assessment. The mean difference in the "pain index" per group was calculated by comparing the values from the initial assessment with the values from the ten-day and the three week assessments Table 30

Twentytwo patients were excluded from the analysis as they refused treatment Four patients were initially randomly allocated to the physiotherapy group and 18 patients were allocated to the "placebo" group Since a predominance of patients from the "placebo" group refused treatment, a separate comparison of the duration of the initial episode between the "placebo" patients and the non-treated patients was carried out A chi-square test did not reveal any differences between the two groups ($\chi^2 = 0\ 22$)

Duration of sick-leave during the initial episode of pain

A comparison was carried out between the number of non-sick-listed and sick-listed patients in each treatment group during the first episode of back pain No significant difference was found between the groups

The median duration of absence from work during the initial episode among the sick listed patients was 20 5 days in the Back School group, 26 5 days in the physiotherapy group and 26 5 days in the "placebo" group

When the three groups were analyzed in relation to the total duration of absence from work (median 21 days), there were significantly more patients with a shorter duration of sick-leave in the Back School group compared to the "placebo" group Table 28

Table 28 Sick-leave during the initial episode of pain in the treatment groups Group A = Back School B = combined physiotherapy C = "placebo"

	$\leqslant 21$	> 21 days	total
Group A	37	18	55
Group B	30	31	61
Group C	25	41	66

$\chi^2 = 10\ 44$, df = 2, $p < 0\ 01$

Table 30 Comparison of the mean difference of the "pain index" per group on three occasions of assessment Group A = Back School, Group B = Combined physiotherapy, Group C = 'Placebo".

	Initial – 10 days $\bar{d}$	Initial – 3 weeks $\bar{d}$
Group A	15 10	15 21
Group B	19 22	17 20
Group C	12 52	17 53

When comparing the mean values of the Back School and physiotherapy groups with the mean value of the "placebo" group, a similar mean decrease of pain was observed in all three groups on the two occasions of assessment following the initial assessment

Recurrences of pain in one year

Number of recurrences

The number of patients in each treatment group with no recurrences was compared with the number of patients with recurrences during one year 36 % of the patients in the Back School, 40 % of those in the physiotherapy group and 29 % in the "placebo" group had no recurrences during one year No relation was found between the type of treatment given and the incidence of recurrences. The median number of recurrences in one year was 2 75 in the Back School group, 2 75 in the physiotherapy group and 2 25 in the "placebo" group On comparison of the number of recurrences in the different groups no relation was found between the type of treatment given and the number of recurrences of pain

Total duration of recurrences of pain in one year

The median number of days of recurrences for the three groups together was 27 days. No significant differences were detected when comparing the total length of recurrences in days during one year in each group

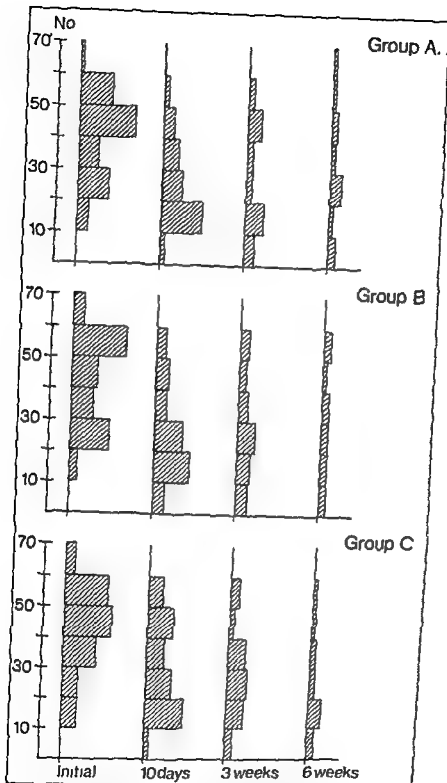

Fig 20 The change of pain in the treatment groups during six weeks as determined by means of the "pain index". The range of scores of the "pain index" is 0 – 70 points

DISCUSSION

GENERAL DISCUSSION

When interpreting the results of this study certain general limitations of clinical research of this type have to be considered

The requirement of blindness in this type of a study is difficult to fulfill when the patients are aware of what treatment they are subjected to It is also difficult to guarantee that the patients do not reveal the treatment received to the assessing physician In a study by Doran and Newell (1975) it was found that the assessing physician inadvertently discovered the treatment in 10 % of the cases No systematic control of the number of patients reporting their treatment was carried out in this study

The reliability of information obtained from the patient has been investigated by Westrin et al (1972) They came to the conclusion that the information could be influenced by the investigator as well as by the investigated individual

The validity of diagnoses of low back pain may also be questioned in view of the lack of knowledge regarding the pathophysiology of low back disorders *In this study an attempt was made to achieve homogeneity of* diagnosis in the studied group by only including patients with 1) pain in the lumbar region with or without sciatica to the thigh, 2) a duration of symptoms not exceeding three months, 3) a pain free year preceding the current episode

However nothing can be said with certainty about the homogeneity of the underlying causes of the pain in the studied group

The lack of knowledge about the etiology of back pain also makes it difficult to find objective methods of assessing clinical manifestations Thus the clinical methods available for measuring the mobility of the spine or the strength of certain muscles lack normal value Furthermore, when pain is present the difficulties in obtaining objective values increase, since the methods for registering pain are inadequate Hence, at an examination the [illegible]

and [illegible]

Total duration of absence from work in one year owing to recurrences

The number of patients not reporting sick during relapses was compared to the number of patients who were sick-listed in the different treatment groups 51 % of the patients in the Back School, 49 % of those in the physiotherapy group and 46 % of the "placebo" group were not absent *from work during one year because of recurrences The median number* of days of sick leave owing to recurrences in one year was 7 5 days in the Back School group, 7 5 days in physiotherapy group and 8 days in the "placebo" group No significant differences were found between the groups

Development of chronicity, rhizopathy, and lumbar insufficiency

The distribution of patients developing chronic pain, rhizopathy and lumbar insufficiency in the three treatment groups is demonstrated in Table 31

Table 31 Development of chronic pain rhizopathy and lumbar insufficiency

	Group A	Group B	Group C	Total
Chronicity	4	4	2	10
Rhizopathy	5	7	6	18
Lumbar insufficiency	44	46	45	135

Change of occupation

More than half of the 217 patients changed their jobs during the year of observation More patients changed jobs in the "placebo" group (61 %) compared to the *Back School patients and the physiotherapy group* (50 %, 46 %) Also the patients changed their jobs because of back pain more frequently in the "placebo" group (27 %) than in the other treat ment groups (10 %, 14 %)

The median age of the patients was 34 5 years, which agrees fairly well with what is known about the age distribution of back pain in the general population (Hult 1954, Hirsch et al 1969, Horal 1969, Kelsey 1975) Back pain is known to be about equally common in men and women (Horal 1969, Kelsey 1975) In this study 13 % of the patients were women, while 20 % of the employees at Volvo are women The design of the study does not admit prevalence analyses, however

The median duration of symptoms before entry of the patients to the study was only 9 days, and 43 % of the patients had never had any episodes of back pain before This is a consequence of the efforts to include only acute and subacute cases without a tendency to chronicity Anamnestic statements on history of back pain have been shown to be subject to uncertainty, however, and the history is often more extensive than the patient has reported (Westrin et al 1972)

Almost half of the patients had a sudden onset of pain, often in connection with a specific incident, an observation that is in agreement with several other reports (Seager 1959, Glover 1960) Lifting and bending manoevres have often attracted interest as provoking factors In this study they were reported in connection with onset of back pain in about 15 % each, and were the most common provoking factors Hult (1954) found that 15 – 20 % of lumbago patients reported onset of symptoms in connection with lifting. In the present study onset of symptoms occurred slightly more frequently during leisure time than during workinghours

The subjective symptoms were penetrated by means of questions about the intensity and character of the pain and consequent functional limitation The questions regarding pain intensity were similar to those used by Horal (1969) In the present series 67 % of the patients thought that their pain was intense, while 84 % of the probands in Horal's study had experienced intense pain in their backs on some occasion This indicates that the patients in the present study had a severity of pain that at least corresponded to an "average" episode of lumbago This is also supported by the fact that about half of the patients had continuous pain through out the day and night, which is similar to what Horal has reported for the probands in his study The functional limitation was studied by 10 questions with 4 alternative answers to each The three most commo[illegible]

[illegible]

An investigation of a multifactorial disorder like low back pain may be characterized by an abundance of soft variables the influence of which is not always easy to determine

PATIENT PROFILE

In this part of the report the distribution of demographic, clinical, vocational, psychological and social factors among the patients is presented The sources of data contributing to the patient profile are of different kinds Three classes of information, with different modes of collecting and differing reliability, can be distinguished

1 Patients' own statements

a with undoubtedly good reliability
This class comprises information about age and certain checkable and unequivocal vocational data such as category of employment and the occurrence of shiftwork

b With unknown reliability
The majority of data making up the patient profile are of this kind This includes information about the history of back pain, mechanism of onset, the condition of pain, certain social and vocational factors and also results of the psychological tests This type of information can be influenced by errors characterizing either the investigator or the investigated individuals themselves (Westrin et al , 1972)

2 Clinical findings

Objective clinical findings are subject to the investigators judgement and measurement There is a certain amount of error involved in registering the clinical findings, but as this has been done by one investigator only in this study, the shortcomings will tend to be uniformly distributed

3 Information from authorities

Information has been obtained from the National Health Insurance Office and from the social welfare authorities Information from the former has good reliability Information from the latter has good reliability regarding the presence of the studied factors among those who have been registered by the authority, but not regarding the absence of these factors among those who have not been registered

at Volvo are manual workers The design of the study does not permit any conclusions about the frequency of low back pain among different categories of employees in industry, but it is interesting that this slight overrepresentation of manual workers is in good agreement with several reports about the occurrence of low back pain in different occupations (Hult 1954, Rowe 1969) The length of employment for the patients was fairly long 72 % had been employed for more than three years and only 4 % had been employed for less than 1 year Since we do not know whether the patients in the material are representative of all Volvo employees with back pain, we cannot draw any conclusions about the length of employment and occurrence of back pain on the basis of these figures, but Magora (1970) found a positive relation between years of employment and frequency of back pain Without drawing any firm conclusions, it is also interesting that shift work was not more common among the patients than among all manual workers at Volvo

Manual workers were subjected to a greater strain from an ergonomic point of view, with frequent bending and twisting movements, less variation and consequently more back fatigue than the office staff On the other hand, the level of satisfaction with the vocational situation seemed to be about equal for both categories of employees

Data describing social conditions were obtained partly from questionnaires and partly from authorities The reliability of these two types of information has been briefly discussed earlier The questionnaires penetrated basic family circumstances, psychosomatic symptoms and also the patients' habits as regards physical exercise Although these questions only give a superficial picture of social conditions, they indicated normal family conditions for the majority of the patients Psychosomatic symptoms occurred infrequently Half of the patients took part in physical exercise Contact with the social authorities since 1974 could be established for 12 % of the patients. The average total duration of sick leave under various diagnoses was 15 5 days per year for the last two years before entry to the study This is less than the average for industrial workers in Göteborg (NHIO-statistics) With the reservation that answers to questionnaires and the absence of contact with social authorities does not exclude social problems, the findings indicate that social problems were not prominent in this study In several other investigations on back pain (Natvig 1970 Westrin 1970 Helander 1973) a lot of social prob-

forwards painful, but could be done (80 %) 3. Sitting painful, but not impossible (73 %) That the sitting posture is so frequently considered painful is consistent with knowledge of the biomechanical loads on the spine in different postures (Nachemson & Elfström 1970)

The frequency of a positive SLR-test is partly a question of definition In this study a positive SLR-test was defined as pain in the back, when the straight leg was raised With this definition 62 % of the patients had a positive SLR-test, but only 14 % of the patients had a positive SLR-test below 60 degrees Magora (1975) reported a positive SLR-test in 20 % of the patients with low back pain.

The range of spinal flexion, extension and lateral flexion was evaluated by objective methods in the sense that the investigator estimated the range of movements by measurements between defined points Moll and Wright (1971) have confirmed the validity of these methods Rotation was estimated by a method where-by the deviation of a plane through the shoulders from an imaginary zero line was measured with a goniometer. This method cannot be considered completely objective The mean values in this study for lumbar extension and lateral flexion were in close correspondence to the mean values that Moll and Wright (1971) have reported for a normal male population of 35 years of age The mean value for lumbar flexion was lower than the mean value in that normal population, however This is probably a consequence of the fact that 89 % of the patients had increased pain on flexion, while provocation of pain occurred less frequently in the other planes of movements In fact, aggravation of pain on lumbar flexion was the most common clinical finding Pain on palpation and percussion was reported by 60 % and 39 % respectively, while postural scoliosis and muscle spasm occurred in less than 20 %

Data describing vocational factors consist partly of unequivocal information e g category of employment, shift work and length of employment Information about ergonomic load has been obtained from questionnaires and is not based on objective measurements This method, with similar questions, has previously been used by Magora (1972, 1973) in an extensive study Finally there is purely subjective information about the patients' satisfaction with their jobs and their opinions about the physical and psychological strain in their work The proportion of manual workers among the patients was 73 %, while 65 % of all employees

at Volvo are manual workers The design of the study does not permit any conclusions about the frequency of low back pain among different categories of employees in industry, but it is interesting that this slight overrepresentation of manual workers is in good agreement with several reports about the occurrence of low back pain in different occupations (Hult 1954, Rowe 1969) The length of employment for the patients was fairly long 72 % had been employed for more than three years and only 4 % had been employed for less than 1 year Since we do not know whether the patients in the material are representative of all Volvo employees with back pain, we cannot draw any conclusions about the length of employment and occurrence of back pain on the basis of these figures, but Magora (1970) found a positive relation between years of employment and frequency of back pain Without drawing any firm conclusions, it is also interesting that shift work was not more common among the patients than among all manual workers at Volvo

Manual workers were subjected to a greater strain from an ergonomic point of view, with frequent bending and twisting movements, less variation and consequently more back fatigue than the office staff On the other hand, the level of satisfaction with the vocational situation seemed to be about equal for both categories of employees

Data describing social conditions were obtained partly from questionnaires and partly from authorities The reliability of these two types of information has been briefly discussed earlier The questionnaires penetrated basic family circumstances, psychosomatic symptoms and also the patients' habits as regards physical exercise Although these questions only give a superficial picture of social conditions, they indicated normal family conditions for the majority of the patients Psychosomatic symptoms occurred infrequently Half of the patients took part in physical exercise Contact with the social authorities since 1974 could be established for 12 % of the patients The average total duration of sick leave under various diagnoses was 15 5 days per year for the last two years before entry to the study This is less than the average for industrial workers in Goteborg (NHIO-statistics) With the reservation that answers to questionnaires and the absence of contact with social authorities does not exclude social problems, the findings indicate that social problems were not prominent in this study In several other investigations on back pain (Natvig 1970, Westrin 1970, Helander 1973) a lot of social prob-

lems have been present The present study and the studies referred to deal probably with populations of back pain patients that are somewhat different The previous studies include chronic cases, while only acute and subacute cases were included in the present study Furthermore, as this study was performed at a factory only patients who were permanently employed were included

There are several reports in the literature about the use of the MMPI for evaluation of psychological factors associated with back pain (Hanvik 1950, Beals & Hickman 1972, Sternbach et al 1973, Timmermans & Sternbach 1974, Wiltse & Rocchio 1975) In groups of patients with long standing back pain the Hs- and Hy-scales seem to be regularly elevated in comparison with normal individuals Furthermore, back pain patients have been found to have higher values on these scales than other patients with pain and functional limitation, e g fracture patients and patients with rheumatoid arthritis (Phillips 1964, Beals & Hickman 1972, Sternbach et al 1973) In the present study the Hs- and Hy-scales of the MMPI were modified for Swedish conditions by exclusion of some questions The scores on the Hs scale were normally distributed, while the scores on the Hy-scale were shifted towards the lower end of the scale Since there is little experience of this test in Sweden, and consequently a lack of adequate reference values, and since the scales were modified, no comparisons have been made of the distribution of the scales in this study with that in normal populations The scales were only used to distinguish between different groups of patients who were compared with regard to the course of the disease This will be discussed below There are no reports in the literature about the distribution of the scales of the Eysenck-test among patients with back pain, but the test has been used for several years in Sweden in psychological practice In this study the Extroversion scale was normally distributed, while the Neuroticism scale was shifted towards the lower end of the scale The distribution of the scales does not differ from the distribution in a normal population (Bederoff Petersson et al 1968)

COURSE OF THE DISEASE DURING 1 YEAR

At the follow up examinations the patients reported whether they had recovered or not, and if they had recovered, they were asked to try to

state on what date the recovery had occurred The patients were classified as having recovered when they did not have pain every day, evoked by normal, every day exertion If they only had stiffness or fatigue in the back or pain evoked only by extraordinary exertion, they were defined as having recovered, but as having symptoms of lumbar insufficiency This demarcation gives some uncertainty as the results might be influenced both by the patient's statements, and by the investigator's judgement Since there was only one investigator in the study, any errors of judgement will tend to be uniformly distributed among the patients

35 % of the patients recovered within one month, 70 % within 2 months and 86 % within three months 6 % had a duration of pain longer than 6 months The recovery rate within 1 month is a little low in comparison with several other reports (Horal 1969, Nachemsson 1976) This might be explained by the fact that only a minority of patients with very short duration were included in this study The recovery rate at two months and later is in fairly good correspondence to that in other reports (Horal 1969, Nachemsson 1976)

The information about sick listing during the initial episode and during relapses has been checked with the National Health Insurance Office 85 % of the patients were sick listed during the initial episode, but the duration of sick leave was considerably shorter than the period of pain There was a significant relation ($p < 0\ 001$) between the duration of pain and duration of sick listing during the initial episode, however When studying sick listing it is important to remember that it does not solely reflect the severity of the condition It is also influenced by various vocational, social and personality-related factors.

The patient's description of pain location was mapped and coded by the investigator The distribution of pain location among the patients on the different occasions of investigation showed a remarkable uniformity within the group during 6 weeks The only divergence was a slight increase in radiation of pain at 6 weeks, which may be a consequence of the fact that 8 % of the patients developed rhizopathy during the year of observation

The pain index is the sum of scores for several indices of pain and functional limitation The more severe the patient's description of the pain was, the higher was the pain index Median values for the pain index at the initial examination were compared with median values for the pain

index at the subsequent investigations. There was a reduction of the pain index by 50 % between the initial examination and the 10 days examination, after which the pain index remained almost stable at the following two examinations It is uncertain whether the change during the first 10-day period represents a true change in the patient's condition or an altered attitude to the questions concerning pain, or a combination of these two factors

After recovery from the first episode, the patients were followed up by further examinations and asked about relapses. 62 % had one or more relapses, and 18 % had more than two relapses On an average, the reported relapses were more benign in character than the initial episode When the relapses for each patient were totalled the median duration was 27 days, which is one week less than the median duration for the initial episode 50 % of the patients with relapses were sick-listed, while 85 % of the patients were sick-listed during the initial episode

62 % of the patients had symptoms of lumbar insufficiency either in connection with recovery from the initial episode or later Hult (1954) reported that 26 % of a group of patients with low back pain also had symptoms of lumbar insufficiency The discrepancy in the incidence of insufficiency in the two studies might be explained by the prospective nature of the present study A prospective study allows better possibilities of detecting even transient episodes of back pain and slight symptoms of lumbar insufficiency Since there are very few prospective studies on low back pain in the literature, the results of the present study are not directly comparable with those of other studies

INFLUENCE OF CONFOUNDING FACTORS ON COURSE OF DISEASE

Many of the factors contributing to the patients' profile were related to the course of the disease

History of back pain

Patients without previous episodes of back pain had a shorter duration of recurrences than patients with up to three previous episodes ($p < 0.05$) On the other hand, the 15 patients who had more than 3 previous episodes tended to have a shorter duration of recurrences than patients without previous episodes of back pain This relationship is very uncertain due to the small number of patients, but it makes it difficult to draw conclusions about the influence of previous episodes on recurrences

Patients with an insidious onset of symptoms had a longer duration of the initial episode than patients with a sudden onset ($p < 0.05$) The relation was rather weak and cannot be considered conclusive, but might be an indication that back pain with different types of onset is in some respect different No answer to this question has been found in the literature

Clinical findings

The severity of symptoms at the initial examination, expressed by the pain index, was related to the duration of sick-leave ($p < 0.05$), but not to the duration of pain When those patients who still had severe symptoms, expressed by a high pain index, after 10 days, were analysed separately there was a stronger relation to the duration of sick leave ($p < 0.001$), and also a relation to the duration of the initial episode of pain ($p < 0.001$) Thus, the intensity of the patients' pain at the first visit is no indication of the duration of pain On the other hand, if severe symptoms have not subsided within 10 days, the duration of the episode will probably be prolonged Quite logically, sick-listing occurred more frequently if the symptoms were severe

When other clinical manifestations, such as radiation of pain to the thigh, decreased lumbar flexion, the presence of postural scoliosis, the presence of pain on percussion and a positive SLR test, were related to the course of the disease it was found that none of them had any influence on the duration of the episode Neither did any of them affect the length of relapses The only relationship found was that both patients with a positive SLR test and those with pain on percussion had a longer duration of sick leave during the initial episode ($p < 0.01$) Consequently, in this study patients with severe symptoms and certain clinical findings had a longer duration of sick leave, but these circumstances did not affect the duration of symptoms or the tendency to relapse On the other hand, if the patients had severe symptoms and these did not subside within 10 days the duration of symptoms was significantly prolonged

Vocational factors

The influence of vocational factors on the course of acute low back pain may be interpreted in terms of more or less strong relations to the prognosis of the disorder The pronounced differences in the course of the disease between the office staff and the manual workers must be of de-

cisive importance when evaluating the relation between vocational factors and the duration of back symptoms and any consequent absence from work

There are probably other possible explanations apart from vocational differences for the significantly shorter duration of the initial episode and the shorter absence from work among the office staff compared to the manual workers

However, the vocational factors related to significantly longer duration of symptoms and absence from work were so highly associated with the working conditions of manual workers only that these vocational factors can not be excluded as having played a part in causing the differences observed between the two categories

Owing to the skewed distributions of vocational conditions and consequent lack of analyses, it is impossible to establish the magnitude of the influence of all the vocational factors on the course of low back pain

Job satisfaction, bending and twisting could not be analysed in relation to each category of employment and the duration of back symptoms

Fixed postures, lifting and forceful movements together with a low requirement of concentration and exhaustion after work were all related to either a prolonged duration of symptoms or absence from work, or both, in the analysis of the whole population These relations were not observed in the separate analysis of manual workers only There is, therefore, no evidence of a strong relation between these variables and the course of acute low back pain among manual workers. These latterly mentioned working conditions were not common enough in the office staff to be analysed separately

For the same reason, daily back fatigue, repetitive and monotonous work could not be related to the course of disease in the office staff only However, daily back fatigue and repetitive and monotonous work were still significantly related to a longer duration of the initial episode in the separate analysis of manual workers Moreover, sitting for less than two hours per day was associated with a prolonged absence from work during the initial episode This prolonged absence from work cannot be explained only by the fact that the patients sat rarely since the patients who stated that they sat for less than two hours per day at the same time reported that their work required standing, bending and twisting postures

most part of the day These vocational circumstances could also explain the prolonged absence from work.

Since the vocational factors studied are strongly related to each other, the results of this study do not reveal which vocational factor or factors are of greatest importance for determining the course of acute low back pain The results only emphasize the need for further investigations in this field

Psychological factors

In the present study the patients filled in a psychological inventory comprising a modification of the Hs and Hy scales from the MMPI test before treatment was begun Six months after entering the study the Eysenck test was administered to the patients A relation was found between a high score on the modified Hy scale and a longer duration of the initial episode and also to a longer duration of sick leave during the initial episode ($p < 0.05$) The Hs scale showed no relation to the course of the disease A low score on the Extroversion scale of the Eysenck test was associated with a longer duration of relapses ($p < 0.05$), while the Neuroticism scale of this test was not related to the course of the disease It is quite logical that the Extroversion scale of the Eysenck test was related to the duration of relapses and not to the duration of the initial episode, since this test was administered to the patients 6 months after their entry to the study

The relations found are weaker than in several of the studies on the predictive capacity of the MMPI (Beals & Hickman 1972, Wifling et al 1973, Wiltse & Rocchio 1975) and cannot be considered conclusive In the previous studies most of the patients had more longstanding back pain than the patients in the present study, and they may differ in respect of the importance of psychological factors Furthermore, the treatment methods were different and the scales of the MMPI that have been used in this study are not identical with the ordinary scales

Although the relationships that have been found are not conclusive, they do indicate that psychological conditions may be of importance even in acute cases To get a definite answer to this, and to elucidate to what extent psychological factors are important, further investigation is necessary

Social factors

As previously mentioned, there are several reports in the literature of an association between back pain and social problems of different kinds (Natvig 1970, Westrin 1970, Helander 1973), but there are few studies that relate these problems to the result of treatment of back pain Roslund (1974) found that the result of surgical treatment for herniated disc was related to the occurrence of preoperative social problems In this study the minority of patients that had a documented contact with the social welfare authorities had a longer duration of the initial episode ($p < 0.01$) The contact with the social welfare authorities mainly took place during the period of the study This means that it is uncertain whether the relation is an indication that patients with social problems tend to have a poorer prognosis or that patients with longstanding back pain gets social problems Irrespective of the origin of the relation, patients with a manifest need for support from the social welfare authorities were significantly more often found among patients with longstanding back pain Considering this fact, it is a little surprising that the occurrence of contact with the social welfare authorities did not influence the duration of sick leave during the initial episode However, in this study the reason for contact with the social welfare authorities has in most cases been constant financial problems, which might have influenced these patients to cut their sick leave as short as possible

Previous psycho somatic symptoms

Patients who had reported "psychosomatic" symptoms of different kinds did not differ from patients without these symptoms as regards the course of the disease This may be compared with Westrin's (1970) findings that psychiatric symptoms were not more common among patients who had been sick-listed for back pain than among controls

Tendency to report sick

Patients with a high rate of sick-listing under various diagnoses during the two years before entry to the study also had a longer duration of sick leave during the initial episode ($p < 0.001$) The duration of pain was not longer for these patients however Consequently, patients with an extensive history of sick leave under various diagnoses had a greater tendency to be sick-listed during the episodes of back pain This is in agreement with the findings of Westrin (1970)

Demographic factors

In this study young patients had a longer duration of the initial episode ($p < 0.05$), and were more often sick listed during relapses, than older patients ($p < 0.05$). This is contrary to other reports (Horal 1969, Haber 1971, Wood & Leish 1974), in which older patients have a more prolonged disability. The findings regarding the influence of age in this study are probably indirect, however, and can be explained by the fact that while the median age in the total material is 35 years, the median age among the office staff, who in this study proved to have a more benign course, is 42.5 years.

There was no difference between the sexes in respect of the course of the disease. This is in contrast to the findings of Leavitt et al. (1971), who reported a poorer prognosis for women in a study on industrial back injury.

The results indicate that clinical findings, both subjective symptoms and objective findings, are of little prognostic value when determining the course of acute low back pain. On the other hand, the results indicate that certain vocational, psychological and social factors are more important when determining the course. However, the magnitude of the prognostic importance of these factors is not possible to establish from the results in this study.

EFFECTS OF THERAPY

Low back pain is often described as periodic in nature with spontaneous remissions (Rowe 1969). The natural history of the disorder must therefore be considered when evaluating therapeutic effects.

This investigation showed that 70 % of the studied group recovered from the initial episode within two months and 86 % within three months, regardless of the treatment given. These figures correspond fairly well with observations by others (Hult 1954, Horal 1969).

The significantly shorter duration of symptoms following the Back School treatment and combined physiotherapy in relation to "placebo" treatment is thus worthy of attention.

Pronounced differences were observed between the group given "placebo" and the two groups given Back School and physiotherapy treatment when using the time following the first treatment as the effect variable

It was therefore of interest to see whether the differences in the duration of symptoms after the first treatment could be explained by corresponding differences in time between the onset of symptoms and first treatment in the treatment groups

The results indicate that the treatment groups did not differ significantly in time for applied treatment in relation to onset of symptoms There is, moreover, a marginal trend indicating that the longer the time elapsing between the onset of symptoms and the start of therapy the longer the time taken after the first treatment until recovery This observation is evidenced by the inclination of the lines in Fig 19 on page 73

The results of the analysis indicate that, with Back School treatment or combined physiotherapy of the type described in this study, patients with acute low back pain recover faster the earlier therapy is instituted

However, the results do not reveal what kind of effect the two modes of therapy have as compared to the "placebo" alternative Since very little is known about the causes of back pain and therefore about the specific effect of therapy, there is reason to expect as pronounced a placebo effect in the Back School and physiotherapy groups as in the "placebo" group

The magnitude of the placebo effect is difficult to measure with present methods The personality of the patient and of the therapist and the time spent with the therapist are probably important factors when one is trying to assess the placebo effect

The significant effect of the Back School in relation to the "placebo" group might to some extent be explained by the fact that the patients spend more time with the therapist in the Back School In both groups the patients are not actively treated and they should therefore be reasonably comparable

The Back School and the combined physiotherapy are more comparable as regards the time spent with the therapist This could be one explanation why there is so little difference in treatment results between the Back School and the combined physiotherapy Physiotherapy as defined

Variations in placebo effect, in compliance and in distributions must also be considered when evaluating absence from work The possibility of skewed distribution of the studied confounding factors is eliminated according to the tables in the appendix mentioned above

The placebo effect and the variation in compliance are factors included, on the other hand, in the significantly shorter absence for the Back School patients This is perhaps not a surprising result since one of the main aims of the Back School is to teach the patients how to work in pain-free postures when the condition of the back so permits.

The reason for using variables related to recurrences as effect variables was to investigate whether preventive measures in the form of the Back School influenced the incidence and length of relapses or consequent absence from work in relation to the other groups. Such an effect was not confirmed by the results, which showed a lack of difference between the three groups A possible effect may, however, be masked by the fact that the patients may have received treatment during recurrences

All the effect variables mentioned so far are quantitative in nature An attempt was also made to compare the treatment groups qualitatively by investigating whether a more pronounced relief of pain could be observed during the course of the initial episode in the studied groups

The corresponding median values and mean differences in the groups do not indicate that any of the three therapies are symptomatically superior to the others

The fact that the patients in the "placebo" group changed occupation because of their back disorders more often than the Back School and physiotherapy patients was a finding which can be subjected to speculative explanations only. Consequently, the differences obtained between the treatment groups in the frequency of changing occupation will not be discussed any further.

At the present stage of research there is a lack of methods for establishing a physiological relationship between the therapy given and the reduction of clinical manifestations. Moreover, the magnitude of a possible placebo effect of therapy on low back pain is unknown

Pending more research in this field, the effect of the Back School and combined physiotherapy should be evaluated with reference to the time and expenses involved in the treatment of low back disorders

on p 31-37 in this study is to a great extent directed towards manual contact with the patient This might also contribute to a further placebo effect. There are other reasons to speculate on the role of the time spent with the therapist. There was no significant difference in duration of the initial episode between the non-treated patients and the "placebo" group. These two groups spend equally short time with the therapist compared to the Back School and physiotherapy patients who spend equally long time with the therapist

Variation in compliance i e the patient's ability and will to comply with directions given is a factor that is as difficult as the placebo effect itself The Back School consists exclusively of lectures. The effect of the School must therefore be seen in relation to the patient's compliance with instructions given

No specific investigation of compliance was carried out in this study, owing to the unsatisfactory nature of the methods available It is possible to determine the retention of theoretical knowledge obtained in the school but this gives no information about the ability of the patients to follow the practical instructions given

The patient's subjective opinion of the value of the Back School has been presented in a study by Lidstrom & Zachrisson (1973) 75 % of the patients reported positive experience of the School

The short duration of symptoms following Back School treatment and physiotherapy in relation to "placebo" must also be elucidated with reference to the previously discussed confounding factors To avoid undesired effects of the confounding factors in the treatment groups, there are several approaches that may be used One is to stratify according to factors known to influence the disorder studied Others (Magora 1970, Sternbach et al. 1973) indicate that vocational and psychological factors are of importance and they were therefore chosen for the stratification in this study Another way to obtain an equal distribution is to study a sufficiently large group The appendix indicates the distribution of confounding factors in the treatment groups. It will be seen that the distribution is equal Thus, the difference in the duration of symptoms following the first treatment in the three groups cannot simply be explained by a skewed distribution of the confounding factors which per se might influence the results

Variations in placebo effect, in compliance and in distributions must also be considered when evaluating absence from work. The possibility of skewed distribution of the studied confounding factors is eliminated according to the tables in the appendix mentioned above

The placebo effect and the variation in compliance are factors included, on the other hand, in the significantly shorter absence for the Back School patients This is perhaps not a surprising result since one of the main aims of the Back School is to teach the patients how to work in pain-free postures when the condition of the back so permits

The reason for using variables related to recurrences as effect variables was to investigate whether preventive measures in the form of the Back School influenced the incidence and length of relapses or consequent absence from work in relation to the other groups Such an effect was not confirmed by the results, which showed a lack of difference between the three groups A possible effect may, however, be masked by the fact that the patients may have received treatment during recurrences

All the effect variables mentioned so far are quantitative in nature An attempt was also made to compare the treatment groups qualitatively by investigating whether a more pronounced relief of pain could be observed during the course of the initial episode in the studied groups

The corresponding median values and mean differences in the groups do not indicate that any of the three therapies are symptomatically superior to the others

The fact that the patients in the "placebo" group changed occupation because of their back disorders more often than the Back School and physiotherapy patients was a finding which can be subjected to speculative explanations only Consequently, the differences obtained between the treatment groups in the frequency of changing occupation will not be discussed any further

At the present stage of research there is a lack of methods for establishing a physiological relationship between the therapy given and the reduction of clinical manifestations. Moreover, the magnitude of a possible placebo effect of therapy on low back pain is unknown

Pending more research in this field, the effect of the Back School and combined physiotherapy should be evaluated with reference to the time and expenses involved in the treatment of low back disorders

The duration of symptoms following the first treatment did not differ significantly in the two treatment groups In addition, the significantly shorter absence from work was observed among the Back School patients

With these findings in mind, there is reason to discuss the demands on resources made by the Back School as compared to combined physiotherapy

The possibility with the Back School of treating several patients at each lesson is the most obvious advantage over combined physiotherapy, which allows only one patient per treatment session

The additional effect of the Back School on the absence from work also favours the use of the Back School system

Judging from the evidence found in this study, relatively small resources in the form of the Back School are sufficient to achieve the same results as therapy requiring more time and personnel.

SUMMARY AND CONCLUSIONS

The aims of this investigation were

1. to describe a population of patients with acute and subacute low back pain. The patients had to meet the following criteria
   a. lumbo-sacral pain, with or without radiation to the thigh,
   b. duration of pain before entry to the trial not longer than three months.
   c. a pain-free year before the onset of the current episode,
2. to determine whether various clinical, vocational, psychological and social factors are of any prognostic value when assessing the course of acute and subacute low back pain,
3. to evaluate the effect of
   a. the Back School, based on ergonomic advice,
   b. combined physiotherapy, consisting of mainly manual therapy,
   c. "placebo", by means of low intensity short wave diathermy,

   on acute and subacute low back pain

This prospective investigation was carried out at the Medical Department of the Automotive Division of AB Volvo, Göteborg, Sweden

Of all patients consulting the Medical Department because of low back pain from August, 1974 to May, 1975, 217 fulfilled the criteria for admission to the trial These patients were all followed for one year. No drop-outs were registered.

The patients underwent a clinical examination and completed a questionnaire about previous back symptoms, current symptoms and their social and vocational situation The patients also underwent psychological tests comprising the Hs- and Hy-scales of the MMPI. The patients were then randomly allocated, on the basis of the psychological tests and vocation-

al factors, to one of the two treatments or to the "placebo" group given low intensity short-wave treatment. After the completion of treatment, the course of the disease was registered at 5 – 7 fixed control examinations during one year. During this period information was also collected from the social welfare authorities and the National Health Insurance Office. The patients were also subjected to a further psychological test, the Eysenck Personality Inventory, six months after entry to the study.

The average age of the patients was 34.5 years and 13 % were women, as compared to 20 % women among all Volvo's employees in Goteborg Just over half the patients had previously suffered from back symptoms in the form of one or more attacks of lumbago or sciatica The duration of the current episode of pain when the patients first attended the medical centre varied between one and 86 days, with a median duration of 9 days. Just over half the patients had a gradual onset of symptoms while the remainder had a sudden onset, often in connection with lifting or bending

All patients had low back pain 26 % had radiation of the pain to the gluteal region or thigh A majority of the patients considered their pain to be intense and half had continuous aching. Coughing and sneezing caused aggravation of the pain in 40 % Pain when leaning forward and sitting was the predominating functional limitation

Straight Leg Raising Test was positive in 62 % of the patients, while only 14 % had a positive test below 60° Almost 90 % of the patients had pain on lumbar flexion, and the mean value for flexion according to a modification of Schober's method was lower than normal The mean values for extension and lateral flexion were within the normal limits and a minority of the patients experienced pain during these movements Pain on percussion was noted in 40 % and tenderness on palpation in 60 % of the patients. Less than 20 % of the patients had a postural scoliosis or pronounced muscle spasm.

27 % of the patients were office staff, which means that they were only slightly under-represented compared to the proportion of office staff among Volvo's employees Sitting predominated as the working posture among office workers and standing among manual workers A minority of both categories of employees considered that their working posture was completely fixed during most of their working day Bending and twisting movements during work were reported by the majority of the

manual workers, whereas lifting and forceful movements were less common A majority of both categories of employees considered that their work required concentration during at least part of the day, whereas variation in the work occurred more frequently among office staff. A majority of the patients considered their work not to be particularly fatiguing. Most of the patients were satisfied with their jobs and with their working environment. 75 % of the patients had been employed at Volvo for more than 3 years.

Of the 217 patients 12 % had had contacts with the social welfare authorities since 1974 owing to financial problems, problems in adjusting or alcoholism Psychosomatic symptoms were infrequent. The total duration of sick-leave during two years before the study was lower than the average for industrial workers.

The distribution of personality variables in the Eysenck test accorded with the distribution in a normal population The hysteria and hypochondriasis scales of the MMPI showed low distributions but no comparison with other populations has been carried out.

The episodes of pain lasted less than one month in 35 % and less than 3 months in 87 % of the patients, while 4 % of the patients still had pain after one year The median duration of pain was 35 days During the initial episode of pain 86 % of the patients were sick-listed with a median duration of sick-leave of 21 days The location of the pain did not alter during the first 6 weeks except that there was a slight increase in the number of cases of radiation of pain at the end of this period. The intensity of pain decreased markedly during the first few weeks, after which it remained relatively constant during the following month in those patients who still had symptoms. Just over 60 % of the patients had a recurrence during the first year, the mean number of recurrences being 1.3 per patient The recurrences were generally less severe and the median total duration of recurrences was 28 days 50 % of the patients with recurrences were sick-listed, the median duration of sick-leave being 16 days

Symptoms of lumbar insufficiency occurred during the follow-up period in 60 % of the patients, while 8 % of the patients developed rhizopathy.

The history of back pain, the clinical manifestations and the vocational, psychological, social and demographic factors characterizing the group

of patients studied were all related to the course of acute low back pain during one year. The course of back pain has been characterized by 1) the duration of symptoms during the initial episode of pain, 2) the duration of sick-leave during the initial episode, 3) the total length of recurrences of pain in one year and 4) the total duration of absence from work due to recurrences in one year.

The number of previous episodes characterizing the history of pain was related to the course of low back pain The duration of recurrences was longer among those patients who had reported up to three previous episodes of pain compared to patients with no previous episodes However, this relationship was not observed among the patients who had had more than three previous episodes of pain These findings indicate that the number of previous episodes of back pain does not play an important part in determining the course of acute low back pain

Patients who reported an insidious onset of pain had a longer duration of the initial episode of pain than the patients who had a sudden onset Back pain may therefore vary in some respect depending on the type of onset

The severity of pain was expressed by a "pain index" based on several questions regarding pain. The scores for the "pain index" on the various occasions of examination were related to the course of back pain A longer duration of sick-leave was observed among the patients who had a high "pain index" score at the initial examination, while the duration of pain initially was not influenced Patients who at the ten-day examination still had an elevated "pain index" score were found to have both a prolonged initial episode and longer absence from work Severe pain mainly predisposes to prolonged sick-leave

Other clinical manifestations, such as radiation of pain to the thigh, decreased lumbar flexion, the presence of postural scoliosis, the occurrence of pain on percussion and a positive SLR-test, were not related to the duration of any of the episodes of pain in one year The only relationship found was a longer duration of sick-leave among patients who had a positive SLR-test and pain on percussion A positive SLR-test and pain on percussion may also be regarded as an expression of pain intensity Consequently, patients with severe symptoms, in terms of both a "pain index" and certain clinical findings, have a longer duration of sick-leave

while the duration of the episodes of pain are not influenced unless the severe symptoms persist.

Vocational factors in terms of working postures required, vocational fatigue, variation, satisfaction and need to concentrate at work, were related to the course of acute low back pain. Frequent bending and twisting, fixed postures, lifting and forceful movements, general fatigue, daily back fatigue, repetitive work, no needs of concentration and discontent at work, were all related to either a longer initial episode of pain or a longer absence from work or both when all the patients were analysed together

A comparison between manual workers and office staff revealed pronounced differences in the duration of symptoms and sick-leave in the two groups The manual workers had both a longer initial episode of pain and a longer duration of sick-leave during both the initial episode and the relapses

Separate analyses of manual workers and office staff were then performed to determine whether the same relationships were observed between the vocational factors and the course of low back pain as in the analysis of the whole group of 217 patients. However, working conditions differed so much between the two groups of employees that the separate analyses did not justify any firm conclusions as to which vocational factor or factors are of the greatest prognostic importance for determining the course of acute low back pain

Patients with high values on the Hy scale in the MMPI had longer episodes of pain and a longer duration of sick leave than other patients, while the Hs scale showed no relation to the course of the disease. Patients with low values on the Extroversion scale in the Eysenck test had a longer total duration of recurrences during one year than those with high values, while the Neuroticism scale was not related to the course of the disease The findings support previous observations that psychological factors are of importance for the course of back pain No firm conclusions about the importance of psychological factors or the mechanism of the causal association can be drawn from the results of this study, however

Patients who had had contacts with the social welfare authorities had a longer initial episode of pain than other patients. This finding accords with previous reports of an association between pronounced back symptoms and social problems, but no conclusions can be drawn as to whether the social problems are a result or a contributory cause of the prolonged course.

Patients who had previously had long periods of sick-leave for different reasons showed a pronounced tendency to have a longer duration of sick-leave during the current episode of pain. The occurrence of certain psychosomatic symptoms was not related to the course of the disease. The patients who regularly engaged in physical training did not differ from the other patients in respect of the course of the disease.

The effect of three different methods of treatment on acute low back pain was evaluated. The Back School was compared with combined physiotherapy and "placebo".

The effect of the treatments was estimated by relating the treatments to 1) the duration of symptoms following the first treatment, with special reference to the time elapsing from the onset of symptoms to the first treatment, 2) the length of absence from work during the initial episode, 3) the change of pain during the initial episode and 4) the number and length and duration of sick-leave owing to recurrences of pain during one year.

The time elapsing from the onset of back pain to the first treatment did not differ significantly in the three treatment groups.

The duration of symptoms following the first treatment was 14.8 days for the Back School group, 15.8 days for the physiotherapy group and 28 7 days for the "placebo" group.

The patients attending the Back School were observed to have a shorter duration of sick-leave during the initial episode than the other two treatment groups. The median absence from work was 20 5 days for the Back School patients, 26 5 days for the physiotherapy group and 26 5 days for the "placebo" group. The change of pain during the initial episode was equal in all the treatment groups. Neither the number, nor the length of absence from work owing to recurrences differed in the three treatment groups

Patients in the "placebo" group changed occupation more often because of back pain (27 %) than the physiotherapy (10 %) and the Back School patients (14 %).

There is enough evidence in this study to conclude that Back School and combined physiotherapy are superior to "placebo" treatment in acute low back pain. The Back School program also reduces the absence from work.

The Back School, teaching several patients at a time, must be regarded as an advantageous mode of therapy as relatively small recources are needed to achieve the same effects as with physiotherapy.

ABSTRACT

A clinical and radiological follow up examination was made in three formerly well examined and defined unilateral samples of Legg Calvé Perthes Disease one group of 100 cases with an average age of 25 years, another of 33 cases with an average age of 35 years, and finally a group of 19 cases with an average age of 65 years

The factors known to influence the shape of the head at the *primary* healing in childhood, sex, age and stage of the disease at time of diagnosis, together with shape of the head at *primary* healing, were examined concerning their influence on the *late* occurrence of radiological coxarthrosis, pain and mobility

Sex and stage had no significant influence on the late fate of the diseased hip Age at onset and shape at the primary healing showed significant influence on the late result

At the 25 and 35 level less than [illegible] per cent had coxarthrosis, and in that case with a significantly higher frequency in irregular healed heads compared to normal and flattened ball shapes

At the 65 level, in an untreated group, there was a high frequency of irregular heads and above 85 per cent coxarthrosis Pain partly arose from the primary healing, partly between 20 to 40 years of age During the decade from 25 to 35 years of age only the irregular shaped heads showed an increase in occurrence of coxarthrosis

CONTENTS

INTRODUCTION

In several previous works on Legg Calve-Perthes' Disease (LCPD), it has been stated that the *primary* shape of the femoral head, at the time of healing, was generally poor in cases not relieved from weight bearing during the active phases of the disease, and also, that the results from treatment were the better the more efficient the non weight bearing was performed (Helbo 1953, Mose 1964, Meyer 1966, Lauritzen 1975) The best results were obtained from prolonged bed rest combined with traction on both legs

Many authors have pointed out identical prognostic factors for the shape of the head at the *primary* healing

- Sex Boys have generally been reported to have better results than girls This was recently denied by the investigation of Lauritzen

- Age at onset of the disease The younger the better results

- Stage of the disease at establishment of diagnosis and treatment On early relief from weight bearing, i e up to early fragmentation the prospects for a good result were better

- Other factors have been mentioned such as different types of course (Catterall) and the degree of destruction during the course of the disease in childhood These factors seem however to depend on the stage of the disease when relief from weight bearing took place

Relatively few reports concern the *late* clinical and radiological results The most important materials were presented by the following authors

Sundt (1949) 153 hips reexamined 10 to 32 years after the onset of the disease

Helbo (1953) 52 unilateral cases examined after more than 25 years

Evans (1958) 52 patients with a follow up from 10 to 26 years with an average of 16 years

Danielsson (1965) 35 patients at an average of 33 years from the onset of the disease to the follow up examination

Ratliff (1967) 34 hips observed for an average of 30 years, variation from 25 to 40 years

Faton (1967) 88 cases comprising of 100 diseased hips, with a follow up averaging 19 years

Gover & Johnston (1971) 36 cases at a mean age of 44 6 years

Steinhauser (1971) 75 cases, among whom 54 had passed puberty'

Brotherton (1977) 102 hips with an average follow up of 17 years

Details of the reports will be mentioned later

The general conclusions of these investigations were, that *primarily irregular* shape of the hip, resulted in a high frequency of late coxarthrosis, whereas *normal ball-shaped* heads never had radiological signs of coxarthrosis nor functional disablement A group between the two mentioned, consisting of still ball shaped but clearly *flattened* heads, were estimated to manage well too

INTRODUCTION

In several previous works on Legg Calve-Perthes' Disease (LCPD), it has been stated that the *primary* shape of the femoral head, at the time of healing, was generally poor in cases not relieved from weight bearing during the active phases of the disease, and also, that the results from treatment were the better the more efficient the non weight bearing was performed (Helbo 1953, Mose 1964, Meyer 1966 Lauritzen 1975) The best results were obtained from prolonged bed rest combined with traction on both legs

Many authors have pointed out identical prognostic factors for the shape of the head at the *primary* healing

- Sex Boys have generally been reported to have better results than girls This was recently denied by the investigation of Lauritzen

- Age at onset of the disease The younger the better results

- Stage of the disease at establishment of diagnosis and treatment On early relief from weight bearing i e up to early fragmentation the prospects for a good result were better

- Other factors have been mentioned such as different types of course (Catterall) and the degree of destruction during the course of the disease in childhood These factors seem however to depend on the stage of the disease when relief from weight bearing took place

Relatively few reports concern the *late* clinical and radiological results The most important materials were presented by the following authors

Sundt (1949) 153 hips reexamined 10 to 52 years after the onset of the disease

Helbo (1953) 52 unilateral cases examined after more than 25 years

Evans (1958) 52 patients with a follow up from 10 to 26 years with an average of 16 years

The general conclusions of these investigations were, that primarily *irregular* shape of the hip, resulted in a high frequency of late coxarthrosis, whereas *normal ball-shaped* heads never had radiological signs of coxarthrosis nor functional disablement A group between the two mentioned, consisting of still ball shaped but clearly *flattened* heads, were estimated to manage well too

NTRODUCTION

n several previous works on Legg-Calvé-Perthes' Disease (LCPD), it has been stated that the *primary* shape of the femoral head, at the time of healing, was generally *poor* in cases not relieved from weight-bearing during the active phases of the disease, and also, that the results from treatment were the better the more efficient the non weight bearing was performed (Helbo 1953, Mose 1964, Meyer 1966, Lauritzen 1975) The best results were obtained from prolonged bed rest combined with traction on both legs

Many authors have pointed out identical prognostic factors for the shape of the head at the *primary* healing

– Sex Boys have generally been reported to have better results than girls This was recently denied by the investigation of Lauritzen

– Age at onset of the disease The younger the better results

– Stage of the disease at establishment of diagnosis and treatment On early relief from weight bearing, i e up to early fragmentation the prospects for a good result were better

– Other factors have been mentioned such as different types of course (Catterall) and the degree of destruction during the course of the disease in childhood These factors seem however to depend on the stage of the disease when relief from weight-bearing took place

Relatively few reports concern the *late* clinical and radiological results The most important materials were presented by the following authors

Sundt (1949) 153 hips reexamined 10 to 52 years after the onset of the disease

Helbo (1953) 52 unilateral cases examined after more than 25 years

Evans (1958) 52 patients with a follow up from 10 to 26 years with an average of 16 years

Danielsson (1965) 35 patients at an average of 33 years from the onset of the disease to the follow up examination

Ratliff (1967) 34 hips observed for an average of 30 years, variation from 25 to 40 years

Eaton (1967) 88 cases comprising of 100 diseased hips, with a follow up averaging 19 years.

Gover & Johnston (1971) 36 cases at a mean age of 44 6 years

Steinhauser (1971) 75 cases, among whom '54 had passed puberty'

Brotherton (1977) 102 hips with an average follow up of 17 years

Details of the reports will be mentioned later

The general conclusions of these investigations were, that *primarily irregular* shape of the hip, resulted in a high frequency of late coxarthrosis, whereas *normal ball-shaped* heads never had radiological signs of coxarthrosis nor functional disablement A group between the two mentioned, consisting of still ball shaped but clearly *flattened* heads, were estimated to manage well too

It was *the purpose* of the present investigation to study the influence on the *late* fate of the affected hip by

1 such factors that determine the primary shape of the head sex, age at onset of the disease, stage of the destruction at the time of treatment, and

2 the shape of the head at the primary healing

In the following, these factors will be related to late results, especially the occurrence of radiological coxarthrosis, pain restriction of mobility, walking ability, and social consequences

Finally it was attempted to estimate the age at which pain and other disablement commenced

A comparison between methods of treatment was not intended

PATIENTS

Patients were traced from three previous Danish theses on LCPD Flemming Møller (1924), Sven Helbo (1953) and Knud Mose (1964)

Moller This thesis was based upon a thorough examination of 72 children or young adults At that time the LCPD was a newly described condition, therefore, many of the cases comprised in Moller s work were diagnosed after the age of 10 In this way the material comprised several cases attacked before the year 1910

The case histories were, unfortunately, not provided with sufficient data as to make it possible to trace the patients Only *8 unilateral cases* originally followed at the University Hospital and other hospitals in Copenhagen could be found by the indefatigable search by Dr Johannes Meyer in the Rigsarkivet (Records Office at the Royal Library) in Copenhagen

Helbo s work comprised a description and the results of the primary course of 66 cases treated between 1941 and 1951 at the Seaside Hospital at Refsnæs

They were all treated for one year with bed rest

Of this material *33 cases* could be traced for the present study

In addition, *Helbo* made an evaluation of long term results in 52 cases, partly based on the patients of Moller partly on former cases treated on the Seaside Hospital at the same time as Moller s cases

From this second group *11 cases* with an observation time of more than 40 years met for re evaluation in the present study

Mose presented three groups, 219 hips in all One group was treated with 'strict bed rest' (78 hips), another with 'mobilizing bed rest (70 hips) and the third group with a Thomas Splint type of walking calliper (71 hips) In every case the patient was treated through the whole period with presumed weakness of the epiphysis, i e for up to two or three years

The cases were taken from the same period, 1953 to 1957 Only the first two groups mentioned were searched for the present study Among these, *100 cases* met for re examination

In the 1964 evaluation there was found no statistical difference in the distribution of good fair and poor primary radiological results between these two bed rest treated groups Thus, in the present study they could be put together in one group

The age distribution mean age and time interval from the mean age at *primary healing* to the mean age at *follow up examination* was set up in Fig 1–3

The three groups prepared for comparison concerning the late fate of the diseased hips were mentioned thus

25 – group 100 unilateral cases from the thesis of Mose

35 – group 33 unilateral cases from the thesis of Helbo

65 – group 19 unilateral cases, 8 from the thesis of Moller, 11 from the thesis of Helbo

The data of all patients from Helbo s and Mose s groups could be found through the State Central Person Register A comparatively large number of cases in these groups did not reply on the application form, probably due to the higher rate of activity in these age groups

It was *the purpose* of the present investigation to study the influence on the *late* fate of the affected hip by

1 such factors that determine the primary shape of the head sex, age at onset of the disease, stage of the destruction at the time of treatment, and

2 the shape of the head at the primary healing

In the following, these factors will be related to late results, especially the occurrence of radiological coxarthrosis, pain, restriction of mobility, walking ability, and social consequences

Finally it was attempted to estimate the age at which pain and other disablement commenced

A comparison between methods of treatment was not intended

PATIENTS

Patients were traced from three previous Danish theses on LCPD Flemming Møller (1924), Sven Helbo (1953) and Knud Mose (1964)

Møller This thesis was based upon a thorough examination of 72 children or young adults At that time, the LCPD was a newly described condition, therefore, many of the cases comprised in Møller's work were diagnosed after the age of 10 In this way the material comprised several cases attacked before the year 1910

The case histories were, unfortunately, not provided with sufficient data as to make it possible to trace the patients

Only *8 unilateral cases* originally followed at the University Hospital and other hospitals in Copenhagen could be found by the indefatigable search by Dr Johannes Meyer in the Rigsarkivet (Records Office at the Royal Library) in Copenhagen

Helbo's work comprised a description and the results of the primary course of 66 cases treated between 1941 and 1951 at the Seaside Hospital at Refsnæs

They were all treated for one year with bed rest

Of this material *33 cases* could be traced for the present study

In addition *Helbo* made an evaluation of long term results in 52 cases partly based on the patients of Møller, partly on former cases treated on the Seaside Hospital at the same time as Møller's cases

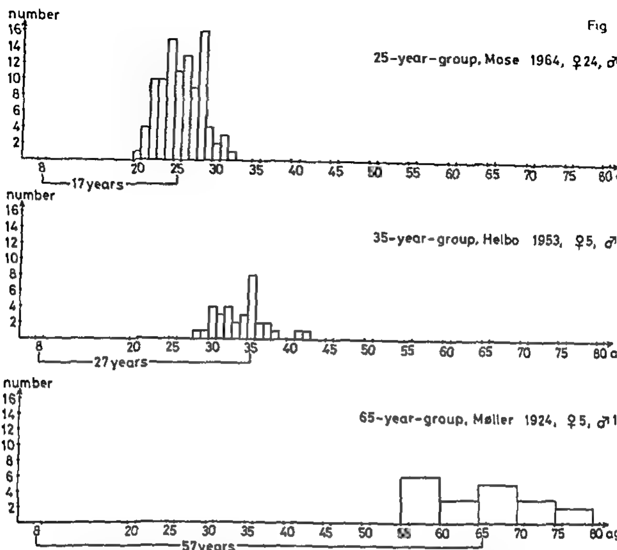
From this second group *11 cases* with an observation time of more than 40 years, met for re evaluation in the present study

Mose presented three groups, 219 hips in all One group was treated with 'strict bed rest' (78 hips), another with 'mobilizing bed rest' (70 hips) and the third group with a Thomas Splint type of walking calliper (71 hips) In every case the patient was treated through the whole period with presumed weakness of the epiphysis, i e for up to two or three years

The cases were taken from the same period, 1953 to 1957 Only the first two groups mentioned were searched for the present study Among these, *100 cases* met for re-examination

In the 1964-evaluation there was found no statistical difference in the distribution of good fair and poor primary radiological results between these two bed rest treated groups Thus, in the present study they could be put together in one group

The age distribution, mean age and time interval from the mean age at *primary healing* to the mean age at *follow up examination* was set up in *Fig 1–3*



The three groups prepared for comparison concerning the late fate of the diseased hips were mentioned thus

25 – group 100 unilateral cases from the thesis of Mose

35 – group 33 unilateral cases from the thesis of Helbo

65 – group 19 unilateral cases, 8 from the thesis of Møller, 11 from the thesis of Helbo

The data of all patients from Helbo's and Mose's groups could be found through the State Central Person Register A comparatively large number of cases in these groups did not reply on the application form, probably due to the higher rate of activity in these age groups

The 19 cases from the 65-group were discovered through Rigsarkivet All cases found met for the follow up examination

Statistical notes on the groups

An examination was made concerning the homogeneity between the three test samples with respect to the three factors influencing the primary results, sex, age at onset of the disease and stage at treatment

– Sex homogeneity certified in the three groups
(χ^2 (2) = 1 3136, p>0,50)

– Age at onset of the disease it was *not* likely to presume homogeneity between the three groups, as there was found relatively fewer observations in the young age groups and relatively more in the age group from 5–8 years in the **35**-group, than in the other two groups
(χ^2 (4) = 13 0040), 0 01<p<0 025

– Stage at diagnosis and treatment homogeneity certified in the two groups treated
(χ^2 (1) = 0 7634, p>0 50)

The discovery of lack of homogeneity between the groups concerning age, may be due to slight differences in the estimation of the time of commencement, which was based on judgement partly on the time of the first complaint, partly on the stage of the disease at the first x-ray picture

PROCEDURE AND METHODS

The follow up *examination* was carried out during the years 1973 and 1974 Radiological and clinical examinations were made on the same attendance, but without the clinician having the opportunity to see the result of the x ray examination before the clinical examination

A Radiology

Examinations were carried out and evaluated by RC and AJ Conventional x ray pictures were taken in frontal view and in frog leg position (lateral view, *Lauensteins projection*)

Furthermore two oblique exposures in erect position were carried out In the first the hip in question was projected anteriorly to the other hip revealing the posterior part of the joint space In the second the examined hip was seen posteriorly to the non examined showing the anterior part of the joint space (Ahlback 1971)

In this way the examination gave detailed information concerning early cartilage destruction

The assessment of the degree of coxarthrosis is given on page 20

Three cases 2 from the 25-group, 1 from the 35 group refused x-ray examination

B Clinical examination

The clinical examinations were carried out by MU and LH They included a careful case history recorded in a *schedule* comprising information necessary for assessment of pain age at onset of pain daily activities etc

The classifications are shown in table 7 and on page 30

The mobility of the hip joint was examined in the following way – *Flexion* in supine position the non examined leg straight out. *Abduction* in supine position both hips being abducted at the same time *Adduction* in supine position, one hip at a time *Rotations* in prone position with knees flexed 90° using the legs as pointers Inward rotation was done with both hips rotated at the same time, outward rotation with the legs one at a time

Atrophy was measured in centimeters

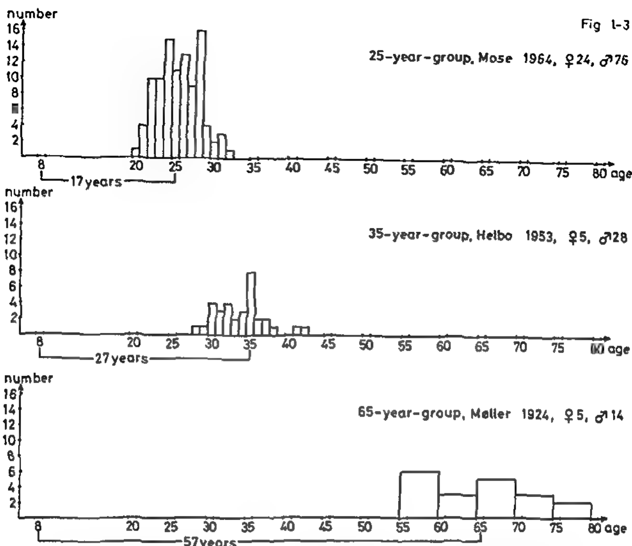
The assessment of the degree of restricted *mobility is given on page 30*

C Radiological measurements

After radiological and clinical examinations, measurements of the shape of the *heads were undertaken by KM*

Measurements were taken from the exposures from the time of primary healing and from the follow up examination

By means of a circle templet, the shape of the hips could be divided into *irregular* and ball shaped heads as described among others by Mose (1964) The latter group *was divided into two subgroups by means* of the templet *flattened ball-shape* and *normal ball-shape* according to the radius quotient (RQ) described by Meyer (1966)



$$RQ = \frac{\text{radius of diseased head}}{\text{radius of normal head}} \times 100$$

In normal persons the RQ may amount to 115

By this procedure three groups were defined

1 irregular heads
2 flattened ball shaped heads, *RQ above 115*
3 normal ball shaped heads, *RQ below 115*

In Moller s cases the x ray pictures from primary healing could not be traced, therefore, the estimation was restricted to ball shaped or irregular heads on the basis of informations given by Moller or by Helbo

The 19 cases from the 65-group were discovered through Rigsarkivet All cases found met for the follow up examination

Statistical notes on the groups

An examination was made concerning the homogeneity between the three test samples with respect to the three factors influencing the primary results, sex, age at onset of the disease and stage at treatment

– Sex homogeneity certified in the three groups
(χ^2 (2) = 1 3136, p>0,50)

– Age at onset of the disease it was *not* likely to presume *homogeneity between* the three groups, as there was found relatively fewer observations in the young age groups and relatively more in the age group from 5–8 years in the 35-group, than in the other two groups
(χ^2 (4) = 13 0040), 0 01<p<0 025

– Stage at diagnosis and treatment homogeneity *certified in the two groups* treated
(χ^2 (1) = 0 7634, p>0 50)

The discovery of lack of homogeneity between the groups concerning age, may be due to slight differences in the estimation of the time of commencement, which was based on judgement partly on the time of the first complaint, partly on the stage of the disease at the first x-ray picture

The RQ is a reliable and easily made estimation of the shape of the head.

Among the other methods described to evaluate the degree of flattening, the epiphyseal quotient (EQ) was excluded because the epiphyseal line has disappeared at the time of follow up examination.

The joint surface quotient (JSQ) requires the drawing of some construction lines, making it less practical for future clinical use, and endows it with some degree of estimation

A combination of the three quotients, demanding the best result in each of the measurements for the single hip to be put into an ideal group, has been used in some works on the primary results. In the present work it was thought to be too strict a measurement to reflect upon the late clinical findings, which may be difficult to define with an equal accuracy.

Age group at follow up ex	at primary healing			at follow up examination		
	25	35	65	[illegible]	35	65
Normel ball shaped	35	16	3	63	17	4
Flattened ball shaped	39	8		12	5	1
Irregular	26	9	13	24	10	14
	100	33	16	99	32	19

Table 1 Number of cases changing from RQ above 115 to RQ below 115 from primary healing to time of follow-up

Statistical notes

In order to investigate the evolution of the RQ between the primary and the secondary examination a paired t-test (two-sided) was performed The original observations were analysed by calculating the difference x = secondary RQ — primary RQ

*Only the **25** and the **35** groups could be examined The difference between the RQ evolutions in the two groups was investigated by performing a t-test (two-sided) on the two independent samples of differences*

25-group $n_1 = 75$, $\bar{x} = -8\,03$, $s^2 = 66\,7831$
An improvement in RQ was likely to occur
$(t\,(74) = -8\,51,\ p < 0\,001)$

35-group $n_2 = 22$, $\bar{x} = -3\,00$ $s^2 = 53\,7619$
A tendency to improvement in RQ was noted
$(t\,(21) = -1\,81,\ 0\,05 < p < 0\,10)$

Both groups *The same variance of x was noted in the two groups*
$(F\,(74\,21) = 1\,1365\ \ p \simeq 0\,25)$
*Improvement in RQ was greater in the **25**- than in the **35**-group*
$(t\,(95) = -2\,5730,\ p \simeq 0\,01)$

In table 1 the grouping of the *primary* results was compared with the results of the measurements at the secondary examination after the end of growth

Discussion The following was noted

- normal ball-shaped heads were still normal and did not change to flattened or irregular shapes.
- all primarily irregular heads were still irregular at the follow up examination (small differences were due to the few cases who refused x-ray examination)
- a significant improvement in RQ was noted among the ball-shaped heads especially in the 25-group a fall in number of flattened ball-shaped heads and a rise in number of normal sphericity

This must be due to an equal numerical growth in radius in the sound and diseased heads, thus leading to a more normal

proportion between their radii during the growth period up to closure of the epiphyseal line

D Preparation for statistics

The data obtained by the procedures mentioned were arranged in groups and put into KH punch cards by KM The comparisons between the frequencies of the different parameters were formulated by a statistician (EH) The χ^2 test was used in most instances The limits of significance for the χ^2 test were stipulated in this manner

$0.05 < p < 0.10$	tendency
$0.01 < p < 0.05$	possible significance
$0.001 < p < 0.01$	significance
$p < 0.001$	high significance

The p-values will not be repeated in the single schedules

The RQ is a reliable and easily made estimation of the shape of the head

Among the other methods described to evaluate the degree of flattening, the epiphyseal quotient (EQ) was excluded because the epiphyseal line has disappeared at the time of follow up examination

The joint surface quotient (JSQ) requires the drawing of some construction lines, making it less practical for future clinical use, and endows it with some degree of estimation

A combination of the three quotients, demanding the best result in each of the measurements for the single hip to be put into an ideal group, has been used in some works on the primary results In the present work it was thought to be too strict a measurement to reflect upon the late clinical findings, which may be difficult to define with an equal accuracy

RESULTS IN PRESENT STUDY

Radiological coxarthrosis

1 LITERATURE

Sundt (1949) Radiological signs of coxarthrosis was found in 65 hips The primary shape of the heads was divided into four groups spherical, (11, none showed coxarthrosis), oval (56, 16 had radiological coxarthrosis), cylindrical (78, 41 showed coxarthrosis) and angular (8, who had all coxarthrosis)

Helbo (1953) divided the results in whom both primary and late x-rays were available spherical heads 4, (none had radiological coxarthrosis), 23 flattened (20 had coxarthrosis) and 11 angulated heads (coxarthrosis in every case)

Evans (1958) found coxarthrosis in all of 16 poor, i e angulated heads, while 21 fair and 15 good were not affected radiologically

Danielsson (1964) found coxarthrosis in 17 of his 35 cases 13 cases had healed with primarily severe deformities, 8 with moderate, while 14 had only slight or no deformity

Ratliff (1967) gave his results in a summarized pointsystem including both clinical and radiolagical parameters, thus preventing comparison to the single parameters used in this work

Eaton (1967) reported the late results of 100 hips as follows 7 excellent, 54 good, 16 fair and 23 poor (or with arthrodesis)

Gower and Johnston (1971) found moderate and severe degress of coxarthrosis in 9 patients, all of whom had healed with flattened heads

Brotherton (1977) used Ratliffs points system According to this 90 per cent obtained good results at the follow up

No one, except Eaton, dealt with the influence of other primary factors than that of a visual estimation of the primary shape of the head

2 METHOD OF ESTIMATION

The radiological examination and the number of projections in the single patient was mentioned in 'procedure and methods'

The estimation of the degree of radiological coxarthrosis was carried through according to a modified Heripret's scheme (Danielsson 1964)

Osteophytes	none	points 0
	at one pole	1
	few	2
	many	3
Joint space	no narrowing	0
	1 2 mm	1
	2 4 mm	2
	above 4 mm	3
Bone structure		
osteoporosis	according to estimate	points 0—3
hyperdensity	no	0
	slight acetabulum	1
	moderate in caput and acetabulum	2
	marked in caput and acetabulum	3
Cysts	none	0
	single caput and acetabulum	1
	more	2
	several	3

The single case may obtain from [redacted] to 15 points

For practical purposes the cases were finally grouped for statistical arrangement in three categories

Coxarthrosis none	0	points
slight	1–4	-
severe	above 5	-

3 Present results

Total occurence of late radiologial coxarthrosis

In Tab 2 the total number of cases with radiological coxarthrosis was drawn up

age group at follow up ex	points for radiol arthr	number	per cent of whole group
25			
(98 cases)	0	73	75%
	1—4	22	22%
	5—8	2	2%
	9—12	1	1%
	13—15	0	0
35			
(32 cases)	0	22	69%
	1—4	8	25%
	5—8	1	3%
	9—12	1	3%
	13—15	0	0
65			
(19 cases)	[redacted]	1	5%
	1—4	2	10%
	5—8	6	32%
	9—12	3	16%
	13—15	7	37%

Table 2 Number and percentage occurence of radiological coxarthrosis was arranged according to age and degree of radiological coxarthrosis (Three cases refused radiological examination)

Statistics Within the single age group all points from 0—4 and from 5—15 were added The following comparisons were done

25 versus [redacted] no significant differences

25 versus 65 χ^2 (1) = 77 0 high significance

35 versus 65 χ^2 (1) = 31 7 high significance

Discussion It appears that in the two younger groups, both relieved consistently during childhood, there was the same distribution of none, slight and more severe coxarthrosis

For the [redacted] group of untreated cases, the occurrence of radiological coxarthrosis, especially in the more severe types, was significantly higher

RESULTS IN PRESENT STUDY

Radiological coxarthrosis

1 Literature

Sundt (1949) Radiological signs of coxarthrosis was found in 65 hips The primary shape of the heads was divided into four groups spherical, (11, none showed coxarthrosis), oval (56, 16 had radiological coxarthrosis), cylindrical (78, 41 showed coxarthrosis) and angular (8, who had all coxarthrosis)

Helbo (1953) divided the results in whom both primary and late x-rays were available spherical heads 4, (none had radiological coxarthrosis), 23 flattened (20 had coxarthrosis) and 11 angulated heads (coxarthrosis in every case)

Evans (1958) found coxarthrosis in all of 16 poor, i e angulated heads, while 21 fair and 15 good were not affected radiologically

Danielsson (1964) found coxarthrosis in 17 of his 35 cases 13 cases had healed with primarily severe deformities, 8 with moderate, while 14 had only slight or no deformity

Ratliff (1967) gave his results in a summarized pointsystem including both clinical and radiolagical parameters, thus preventing comparison to the single parameters used in this work

Eaton (1967) reported the late results of 100 hips as follows 7 excellent, 54 good 16 fair and 23 poor (or with arthrodesis)

Gower and Johnston (1971) found moderate and severe degress of coxarthrosis in 9 patients, all of whom had healed with flattened heads

Brotherton (1977) used Ratliffs points system According to this 90 per cent obtained good results at the follow up

No one, except Eaton, dealt with the influence of other primary factors than that of a visual estimation of the primary *shape of the head*

2 Method of estimation

The radiological examination and the number of projections in the single patient was mentioned in 'procedure and methods'

The estimation of the degree of radiological coxarthrosis was carried through according to a modified Heripret's scheme (Danielsson 1964)

Osteophytes	none	*points 0*
	at one pole	*1*
	few	*2*
	many	*3*
Joint space	no narrowing	0
	1 2 mm	1
	2 4 mm	2
	above 4 mm	3
Bone structure		
osteoporosis	according to estimate	points 0—3
hyperdensity	no	0
	slight acetabulum	1
	moderate in caput and acetabulum	2
	marked in caput and acetabulum	3
Cysts	none	0
	single caput and acetabulum	1
	more	2
	several	3

The single case may obtain from 0 to 15 points

For practical purposes the cases were finally grouped for statistical arrangement in three categories

Coxarthrosis	none	0	points
	slight	1–4	-
	severe	above 5	-

3 Present results

Total occurence of late radiologial coxarthrosis

In Tab 2 the total number of cases with radiological coxarthrosis was drawn up

age group at follow up ex	points for radiol arthr	number	per cent of whole group
[illegible]			
(93 cases)	0	73	75%
	1—4	22	22%
	5—8	2	2%
	9—12	1	1%
	13—15	0	0
35			
(32 cases)	0	22	69%
	1—4	8	25%
	5—8	1	3%
	9—12	1	3%
	13—15	0	0
65			
(19 cases)	0	1	5%
	1—4	2	10%
	5—8	6	32%
	9—12	3	16%
	13—15	7	37%

Table 2 Number and percentage occurence of radiological coxarthrosis was arranged according to age and degree of radiological coxarthrosis (Three cases refused radiological examination)

Statistics Within the single age group all points from 0—4 and from 5—15 were added The following comparisons were done

25 versus 35 no significant differences

25 versus 65 χ^2 (1) = 77.0 high significance

35 versus 65 χ^2 (1) = 31 7, high significance

Discussion It appears that in the two younger groups both relieved consistently during childhood, there was the same distribution of none, slight and more severe coxarthrosis

For the 65 group of untreated cases, the occurrence of radiological coxarthrosis, especially in the more severe types, was significantly higher

Influence of sex on the late occurence of coxarthrosis was shown *in Tab 3*

Radiol arthr in points	Males		Females	
	number	per cent	number	per cent
0	75	65%	21	64%
1—4	25	21%	7	21%
above 5	16	14%	5	15%
	116		33	

Table 3 Occurence of radiological coxarthrosis arranged according to sex and degree of radiological arthrosis

Three cases refused x ray examination

Statistics χ^2 *(2) = 0 039 No significance*

Discussion The three age groups were regarded as a whole, considering the small number of female cases The distribution of no, slight and severe coxarthrosis was identical between the two sexes Thus, a difference in *primary* results, females having worse results (Mose), had no bearing on the late occurrence of coxarthrosis

Influence of age at onset of LCPD on the occurrence of late radiological coxarthrosis

In table 4 only cases from the 25-*group* and the 35-group were included and the cases regarded together as the two groups were not homogenous concerning age at onset of the disease The mean age for this group as a whole was 27,5 years In the 65-group the age at onset of the disease was not sufficiently defined

Age at onset	≦ 4			5—8			≧ 9		
Degree of radiol coxarthrosis	25 +	35	65	25 +	35	65	25 +	35	65
None	31	86%	0	51	76%	1	13	48%	0
1—4	5	14%	0	15	22%	2	10	37%	0
above 5	0	0	5	1	2%	4	4	15%	7
	36			67			27		

Table 4 Influence of age at onset of LCPD on the late occurence of coxarthrosis The 25 and the 35 groups were united and regarded together (mean age 27 5 years)

Statistics

below 4 versus 5—8 *no statistical difference*

5—8 versus above 9 χ^2 *(1) = 6 9 Significance*

below 4 versus above 9 χ^2 *(1) = 10 5 Significance*

Discussion If all degress of coxarthrosis, whether minor or major, were united, it *would show that onset below 4 years in*volved 14 per cent late coxarthrosis, onset between 5-8 involved 24 per cent and onset above 9 as many as 52 per cent The differences in occurrence of coxarthrosis between both of the two young groups compared to the group above 9 years, were significant This late finding was in accordance with the finding that age at onset greatly influenced the primary result (Mose, Lauritzen)

Influence of stage at onset of treatment on the occurrence of late radiological coxarthrosis

This subject was referred in *table 5*

Stage at treatment	*Early*				*Late*			
Age group	25		35		25		35	
Points for coxarthr	nos	%	nos	%	nos	%	nos	%
0	48	73%	15	83%	25	78%	7	50%
1—4	15	23%	3	17%	7	22%	5	36%
> 5	3	4%	[redacted]	0	0	0	2	11%
	66		18		32		14	

Discussion No significant conclusions could be drawn from this study Only in the 35-group a possible difference was demonstrated between early and late treatment

The fact that early treatment resulted in better *primary* results (Helbo, Mose, Lauritzen) found no reflection in the *late* results in the present study

Table 5 Secondary radiological arthrosis arranged according to stage at relief from weight bearing The 65 group was regarded as untreated and thus excluded from the list

Statistics
Early 25 *versus early* 35 *early* [redacted] *versus late* 25 *and late* 25 *versus late* 35 *No significant difference Early* 35 *versus late* 35 χ^2 *(1) = 4 07 Possible significance*

Influence of the primary shape of the head on the late occurrence of coxarthrosis

An all over view of the per centage distribution of none, slight and severe radiological coxarthrosis, related to primary shape and age groups was shown in the histogram in fig 7

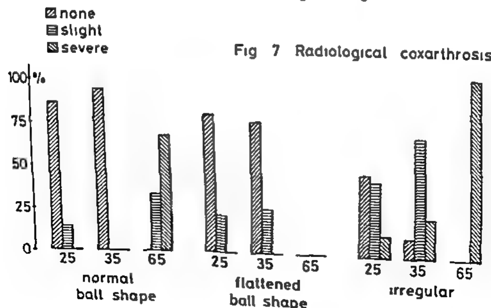

Fig 7 Radiological coxarthrosis

Influence of sex on the late occurence of coxarthrosis was shown *in Tab 3*

Radiol arthr in points	Males		Females	
	number	per cent	number	per cent
0	75	65%	21	64%
1—4	25	21%	7	21%

Influence of the primary shape of the head on the late occurrence of coxarthrosis

An all over view of the per centage distribution of none, slight and severe radiological coxarthrosis, related to primary shape and age groups was shown in the histogram in fig 7

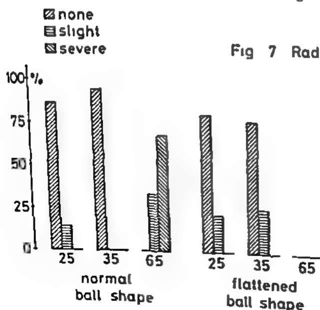

Fig 7 Radiological coxarthrosis

The single numbers and percentages from the histogram were given in table 6 A C

25-group

Points for coxarthr	normal ballshape		flattened ballshape		irregular	
0	30	86%	31	84%	12	46%
1—4	5	14%	6	16%	11	42%
> 5	0	0	0	0	3	12%
	35		37		26	

Table 6 A
Statistics Normal versus flattened No significance Flattened versus irregular χ^2 *(1) = 9 97 Significance Normal versus irregular* χ^2 *(1) = 10 88 High significance*

35 group

	normal ballshape		flattened ballshape		irregular	
0	15	100%	6	75%	1	11%
1—4	0	0	2	25%	6	67%
> 5	0	0	0	0	2	22%
	15		8		9	

Table 6 B
Statistics Normal versus flattened No significance Flattened versus irregular χ^2 *(1) = 7 13 Significance Normal versus irregular* χ^2 *(1) — 20 00 High significance*

65 group

	normal ballshape		flattened ballshape	irregular	
0	0	0		0	
1—4	1	33%		0	
> 5	2	67%		13	100%
	3			13	

Table 6 C
Statistics Ballshape versus irregular χ^2 *(1) = 4 62 Possible significance*

Discussion In the present study no difference in occurrence of late coxarthrosis was found between normal and flattened ball shapes

Both in the **25**- and in the **35**-group, a significantly higher occurrence of cox arthrosis was found among irregular shapes as compared to normal and flattened heads

Furthermore a study was made to see what happened to normal, flattened and irregular hips from a mean age of 25 to that of 35 (comparison vertically between tabel 6 A and 6 B)

Normal **25** versus **35** no significant increase

Flattened **25** versus **35** no significant increase

Irregular **25** versus **35** χ^2 (1) 3 5 By one-tail test this was possibly significant (0 01 < p < 0 05)

By two-tail test a tendency to increase was shown (0 10 < p < 0 05)

Discussion No increase could be shown in occurrence of coxarthrosis from the age of 25 to 35 assuming normal or flattened ball shape For the irregular heads a possible increase in coxarthrosis was demonstrated from 25 to 35 years in mean age

Occurrence of pain

1 Literature

Pain was recorded in earlier investigations as follows

Sundt (1949) reported 17 cases with reduced working capacity and among them 9 with severe complaints out of the material of 135 cases

Helbo (1953) out of his 52 late cases, reported that *only 8 were symptomfree*, while the rest had some disability

Evans (1958) found only 'trivial subjective complaints among 52 cases

Danielsson (1964) among 35 patients found 7 with pain, all of whom belonged to the most deformed cases

Ratliff (1967) noted that four fifths of his 34 hips were free from pain while only two fifths had good hips radiologically

Eaton (1967) out of his 85 non operated cases found *45 without pain, and 22 with* slight 15 with moderate and 3 with severe pain

Gower and Johnston (1971) found absent or mild pain among their 36 cases, only 3 cases having required operation

Steinhauser (1971) 11 per cent who complained of pain were all in poor quotient groups

2 Assessment of pain

The grading of pain was carried through according to a modified Merle d Aubigny statement

1 No pain

2 Pain when starting Capable of moderate work and sport

Requiring treatment

3 Starting pain and pain again after 1500 metres walking Rarely analgesics Demanding periodic treatment (heat etc)

4 Starting pain and pain after 400—1500 metres walking Frequently analgesic and antirheumatic drugs Demands often physical medicine treatment

5 Resting pain and pain before 400 metres walking Analgesics daily

[illegible] Strong persistent pain preventing sleep

Table 7 Assessment of pain

In the present study with its comparatively small number of cases with secondary disablement, distinguishments were only made between three groups

1 No pain

2 Slight pain (group 2)

3 Severe pain, corresponding to pain requiring treatment

3 Present results

Localisation of pain

Pain was complained of in 60 cases, solely in the adductor region in 26 cases, in the trochanteric region in 19 cases, and in both regions in 15 cases, among whom 3 also complained of low back pain The localisations were analysed and showed no specific and statistically significant relation to other parameters, *especially not to radiological coxarthrosis*

Total occurrence of pain

An all over view of the 60 cases having pain was arranged in *table 8*

Age group	[illegible] group		35 group		[illegible] group	
pain	slight	severe	slight	severe	slight	severe
nos	22	10	11	4	2	11
%	22%	10%	33%	12%	10%	58%

Table 8 60 cases complaining of pain recorded according to age group and degree of pain

Statistics

25 *group versus* 35 *group No significant diff*

35 *group versus* 65 *group* χ^2 *(1) = 9 40 Signific*

25 *group versus* 65 *group* χ^2 *(1) = 10 57 Signific*

Discussion Between the 25- and the 35- [illegible]

[illegible] the 65 group had a significantly higher occurrence of pain *especially* in the group of severe pain

Influence of sex on the late occurrence of pain was shown in table 9

Sex	male		female	
number	118		34	
no pain	76	64%	16	47%
slight pain	28	24%	7	21%
severe pain	14	12%	11	32%

Table 9 Occurence of pain related to sex
Statistics χ^2 *(1) = 8 16 Possible significance*

Discussion The females comprised 22 per cent of the whole material, which was in accordance with other materials published The three groups were looked upon as a whole, because of the small number of females compared to males A possible significant preponderance of more severe complaints of pain was noticed

Influence of age at onset of LCPD on the late occurrence of pain

In the 25-, 35- and 65-groups there was found absence of homogeneity concerning age distribution at the onset of LCPD

Comparison (table 10) was therefore made only between the united 25- *and* 35-groups The 65-group, which was in itself small and difficult to compare to the others, was merely added in brackets

Age group at onset	≦ 4			5—8			≧ 9			
group at follow up ex	25+35		(65)	25+35		(65)	25+35		(65)	
no pain	31	82%	(1)	43	64%	(4)	12	43%	(7)	
slight	4	11%	(1)	19	28%	(1)	10	36%	(0)	
severe	3	7%	(3)	5	8%	(2)	6	21%	(6)	86%
	38		(5)	67		(7)	28		(7)	

Table 10 Distribution of patients complaining of pain related to age at onset of LCPD
Statistics »No pain« compared to »slight and severe pain« combined
< 4 versus 5—8 χ^2 *(1) = 3 5 not significant*
5—8 versus > 9 χ^2 *(1) = 3 6 not significant*
< 4 versus > 9 χ^2 *(1) = 10 6 significant*

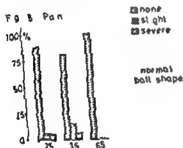
Discussion There was found to be decrease in percentage occurrence of painless hips with increasing age at onset of the disease (82–64–43 per cent) At the same time slight and severe pain increased in percentage occurrence (18–36–57 per cent) These findings were however, only significant when comparing the group below 4 to that above 9 at onset of LCPD The 65 group showed as expected a high frequency of pain in the group attacked late (86 per cent) The numbers were too small for statistical comparisons

Influence of stage at relief from weight bearing on the late occurrence of pain

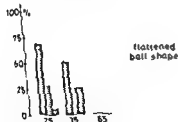
It was attempted to elucidate this subject in *table 11*

Age group	Early 25		Early 35		Late 25		Late 35	
no pain	46	70%	11	58%	22	65%	7	50%
slight	13	20%	5	19%	9	26%	[illegible]	43%
severe	7	10%	3	16%	3	9%	1	7%
	66		19		34		14	

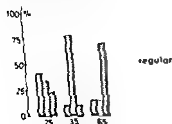
Table 11 Influence of stage at onset of treatment on the late occurrence of pain The 65 group was regarded as untreated



Discussion The influence of early or late commencement of treatment on the late occurrence of pain seemed insignificant This was in accordance with the findings of Eaton (1967)



A clear influence of stage on the *primary* result did not bring its influence to bear on the late result in this study



Statistics All comparisons between the columns showed no significance

Influence of the primary shape of the head on the late occurrence of pain

In the histogram, fig 8 the percentage oc currence of cases complaining of pain was arranged according to primary shape and age groups

Details were given in *table 12*

25 group

	normal ballshape		flattened ballshape		irregular	
no pain	31	89%	26	67%	11	42%

Table 12 C
Statistics Numbers very small Slight and se combined Ball shape versus irregular χ^2 *(1, 8 12 significant*

Discussion A clear change in occurrence of pain from normal to irregular heads was established

For the **25**-group (tab 12 A) there was a gradual fall in 'no pain' from group to group (89–67–42 per cent) and a corresponding rise in occurrence of 'slight and severe pain' (10–33–58 per cent) But only comparisons between normal and irregular shapes were statistically significant

For the **35**-group the same tendencies were demonstrated (tab 12 B)

In the **65**-group a total of 85 per cent of the irregular shapes were estimated to have slight and severe pain The nine cases complaining of severe pain all appeared in the groups above 4 points (see tab 7)

A study was made concerning a possible change from the age of 25 to that of 35 (columns in tab 12 A and 12 B read vertically)

Neither normal nor flattened ball shaped heads showed any significant increase in occurrence of pain during the decade mentioned

In the group of irregular heads there was a tendency towards an increase in occurrence of pain from the mean age of 25 to that of 35

(χ (1) = 2 89, 0 05 < p < 0 10)

Secondary pain was finally correlated to *secondary radiological* coxarthrosis in tab 13

Discussion Convincing correlation was found between radiological coxarthrosis and complaints of pain at the follow up examination

Radiological coxarthrosis	no (96)		slight (32)		severe (21)	
No or slight pain (125)	90	95%	27	84%	8	38%
severe pain (24)	[illegible]	[illegible]%	5	16%	13	62%
	96		32		21	

Table 13 Correlation between degree of radiological coxarthrosis and pain at the time of follow up 149 out of 152 cases accepted radiological examination

Statistics

Slight versus severe $\chi^2 (1) = 12\ 10$ high signif

No versus severe $\chi^2 (1) = 39\ 23$ high signif

AGE AT ONSET OF PAIN

1 Literature

Sundt (1949) reported only 22 per cent symptomfree at the primary healing

Max Ruelle (1961) made a survey of one thousand cases of coxarthrosis with the aim to find the proportion between primary and secondary ostearthrosis, and define the time in life when pain arose

All patients were referred to a rheumatological clinic and the indication for the starting points of complaints was simply the need for treatment

271 cases had ostearthrosis secondary to diseases or traumas during childhood and youth Among these 113 might be like LCPD cases according to the description of Ruelle

The mean age for beginning *secondary* coxarthrosis was found to be 10–44 years the majority of cases occurring between 30 to 50 years of age (76 cases out of 113)

The mean age for beginning *primary* coxarthrosis was 57 years, with a span from 50 to 70 years

Ratliff (1967) found signs of deterioration in pain and movement in 6 patients out of 34, during a period of observation of 12 years from his first to his second examination In the latter the maximum age was 40 years

Present study

60 patients complaining of pain were arranged according to their own statement on the age at onset of pain (table 14)

Age	below 10		10—20		20—40		above 50 years	
degree	slight	severe	slight	severe	slight	severe	slight	severe
	11	*9*	7	*1*	17	*11*	[illegible]	*4*

Table 14 Age [illegible] onset of pain according to the patients own recollection

Discussion The age at onset of complaints was difficult to establish with accuracy in a questionnaire

The pain in the present cases was not as severe as in Ruelles cases in need of treatment This may explain the fall in age group to about 10 years younger in the present material as compared to Ruelles

Cases with severe pain occurred partly from the primary healing in childhood like the findings of Sundt partly from the decades from 20 to 40 years of age

In the years from 10 to 20 pain seldom arose

Both below 10 and from 20 to 40 years of age severe degrees of pain occurred mainly among irregularly shaped heads

Further reference was made to table 12 A statistical tendency to a reversal in occurrence of pain from the 25 to the 35 group was shown in the irregular heads only

The same tendency was shown concerning occurrence of radiological coxarthrosis (table 6 A and B) and of mobility (table 20 A and B)

Thus the present study seemed to support the indications of Ruelle concerning age at onset of pain caused by LCPD in childhood Also Meyer (1977) was of the same opinion Possibly a somewhat earlier beginning for the complaints was demonstrated in the present work This early onset of complaints was, however, limited to irregular heads

Restriction of mobility

1 Literature

Different authors have estimated movement of the hip by a variety of methods, that prevent comparison

Sundt (1949) grouped all degrees of restriction from the slightest to the completely ankylosed hips in one group, and completely free movements in the other

51 cases showed restriction of flexion, 109 of abduction, 45 of adduction, 59 of supi-

Discussion A clear change in occurrence of pain from normal to irregular heads was established

For the **25**-group (tab 12 A) there was a gradual fall in 'no pain' from group to group (89–67–42 per cent) and a corresponding rise in occurrence of 'slight and severe pain' (10–33–58 per cent) But only comparisons between normal and irregular shapes were statistically significant

For the **35**-group the same tendencies were demonstrated (tab 12 B)

In the **65**-group a total of 85 per cent of the irregular shapes were estimated to have slight and severe pain The nine cases complaining of severe pain all appeared in the groups above 4 points (see tab 7)

A study was made concerning a possible change from the age of 25 to that of 35 (columns in tab 12 A and 12 B read vertically)

Neither normal nor flattened ball shaped heads showed any significant increase in occurrence of pain during the decade mentioned

In the group of irregular heads there was a tendency towards an increase in occurrence of pain from the mean age of 25 to that of 35

($\chi^2(1) = 2\ 89,\ 0\ 05 < p < 0\ 10$)

Secondary pain was finally correlated to *secondary radiological* coxarthrosis in tab 13

Radiological coxarthrosis	no (96)		slight (32)		severe (21)	
No or slight pain (125)	90	95%	27	84%	8	38%
severe pain (24)	6	[illegible]	5	16%	13	62%
	96		32		21	

Discussion Convincing correlation was found between radiological coxarthrosis and complaints of pain at the follow up examination

Table 13 Correlation between degree of radiological coxarthrosis and pain at the time of follow up 149 out of 152 cases accepted radiological examination

Statistics

No radiol coxarthrosis versus slight No signif

Slight- versus severe- $\chi^2(1) = 12\ 10$ high signif

No - versus severe- $\chi^2(1) = 39\ 23$ high signif

Age at onset of pain

1 Literature

Sundt (1949) reported only 22 per cent symptomfree at the primary healing

Max Ruelle (1961) made a survey of one thousand cases of coxarthrosis with the aim to find the proportion between primary and secondary ostearthrosis, and define the time in life when pain arose All patients were referred *to a rheumatological* clinic, and the indication for the starting points of complaints was simply the *need for treatment*'

271 cases had ostearthrosis secondary to diseases or traumas during childhood and youth Among these 113 might be like LCPD-cases according to the description of Ruelle

The mean age for beginning *secondary* coxarthrosis was found to be 40–44 years, the majority of cases occurring between 30 to 50 years of age (76 cases out of 113)

The mean age for beginning *primary* coxarthrosis was 57 years, with a span from 50 to 70 years

The same tendency was shown concerning occurrence of radiological coxarthrosis (table 6 A and B), and of mobility (table 20 A and B)

Thus the present study seemed to support the indications of Ruelle concerning age at onset of pain caused by LCPD in childhood Also Meyer (1977) was of the same opinion Possibly a somewhat earlier beginning for the complaints was demonstrated in the present work This early onset of complaints was, however, limited to irregular heads

Restriction of mobility

1 Literature

Different authors have estimated movement of the hip by a variety of methods, that prevent comparison

Sundt (1949) grouped all degrees of restriction from the slightest to the completely ankylosed hips in one group, and completely free movements in the other

51 cases showed restriction of flexion, 109 of abduction 45 of adduction, 59 of supi

nation, 75 of pronation and 65 of hyperextension.

A percentage specification of restriction of movement could not be tabulated, as a summing up of the above mentioned figures did not balance with the total.

Evans (1958) regarded a direction of movement as being limited when it showed a restriction of 10 degrees or less as compared to the normal hip.

14 cases showed limitation in one direction, 3 in two directions, and 10 in three or more directions. 25 hips were completely free. The movements restricted were abduction (17 cases), lateral rotation (17 hips), extension (11 hips) and medial rotation (10 hips).

Danielsson (1964) according to an index system found excellent and good mobility in all cases, whereas none were fair or poor.

Ratliff (1967) found movement full or with terminal limitation in 20 of his 34 cases.

Eaton (1967). In 97 hips not operated upon, 54 were found to have free movement. 23 hips showed 75 per cent reduction in mobility, 13 hips had 50–75 per cent reduction, and 7 hips had below 50 per cent mobility left.

Steinhauser (1971) among 75 cases, referred 7 per cent with limited mobility and 93 per cent completely free.

Gower and Johnston (1971) in their case report referred 4 cases with a total mobility above 260 degrees, 9 cases from 211–260 degrees, and 23 below 210 degrees.

2. Method of estimation

According to the degrees of movement noted at the clinical examination described in page 13, the patients were grouped in the following two ways:

1. Sum of movements	above 260	degrees
–	211 – 260	–
–	161 – 210	–
–	101 – 160	–
–	61 – 100	–
–	0 – 60	–

(This classification was indicated by Harry K. Sorensen.)

2. Limitation of movement in the diseased hip amounted to 50 per cent of the movement in the normal hip in:

   no direction, 1, 2, 3, 4, 5 or 6 directions.

This quite rough 50 per-cent estimate was given in order to avoid such errors as limitation caused by pain, by mental aggravation or by different estimates by the single examiner, etc.

The two methods were correlated in table 15. It is evident that there was accordance between the two criterias of classification (χ (2) = 32.65, $p < 0.005$).

For practical purposes only three mobility groups were used in the following:

Free	sum above 260 degrees
Slight restriction	sum 211 – 260 degrees
Severe –	sum below 210 degrees

No attempt was made to assess the value of the restriction of a single movement by an index system (Danielsson 1964).

Number of directions restricted more than 50 % of the normal	none	1 direction	2 or more
sum of movements			
above 260 (10?)	90	15	[illegible]
211—260 (20)	2	14	4
below 210 (27)	0	3	24
	92	32	28

Table 15 Comparison between two methods of estimation of restriction of movement

Statistics χ^2 (2) = 32 6 significance

3 Present results

A complete review of the occurrence of limitation of movement was arranged in *tab 16*

Age group	25		35		65	
movement						
above 260	79	93 %	22	79 %	4	31 %
211—260	14		5		2	
below 210	7	7 %	7	21 %	13	69 %
	100		33		19	

Table 16 152 cases arranged according to range of movement in degrees and age group at follow up examination

Statistics free and slight combined

[illegible] versus 35 group χ^2 (1) = 5 32 possible signif

35 versus 65 group χ^2 (1) = 9 11 significant

25 versus 65 group χ^2 (1) = 37 92 high signif

Excess of severe restriction in the 65 group

Discussion Restriction of movement to below a sum of 210 degrees occurred with increasing frequency with increasing age

The occurrence of the *single directions recorded as reduced to less than 50 per* cent of the normal side, was shown in tab 17

Age group	25	35	65	sum
flexion	2	0	5	7
abduction	4	2	11	17
adduction	3	3	8	14
outward rot	17	10	11	38
inward rot	22	7	14	43
hyperextension	[illegible]	0	1	1
				160

Table 17 Directions of movement restricted more than 50 % recorded in age groups

From tab 17 it appeared, that rotations were far the most frequent movements to be limited

The following observations may be added

- In cases of *no pain*, 20 directions were limited, all of which were rotations
- In cases with *slight pain* 37 directions were limited Of these 29 were rotations (78 per cent)
- In the case of *severe pain*, 63 directions were reduced

  Among these 32 (51 per cent) were rotations, 14 (22 per cent) abduction, 11 (17 per cent) adduction, 5 (8 per cent) flexion, and 1 (2 per cent) hyperextension

Influence of sex on late occurrence of limitation of mobility was shown in *table 18*

	male		female	
above 260	83	70 %	22	65 %
211—260	14	12 %	6	17 5 %
below 210	21	18 %	[illegible]	17,5 %
	118		34	

Table 18 152 cases arranged according to range of movement and sex

Statistics Three age-groups combined because of the small number of females Homogeneity in distribution between the two columns

Discussion The influence of sex on the *primary* result could not be confirmed concerning the *secondary* result in this study

Influence of age at onset of LCPD on the late occurrence of limitation of movement, was shown in *table 19*

Age at onset	≦ 4			5—8			≧ 9		
age group	25+35		65	25+35		65	25+35		65
above 260	33	87%	1	52	78%	3	16	57%	0
211—260	4	11%	0	10	15%	1	4	14%	1
below 210	1	2%	4	5	7%	3	8	29%	6
	38		4	67		7	28		7

Table 19 Restriction of movement arranged according to age at onset of LCPD and age group at follow up examination

Statistics The 25- and 35-groups combined The 65 group was inserted for comparison Slight and severe added

< 4 versus 5—8 No significance

5—8 versus > 9 χ^2 (1) = 4 06, possible significance

< 4 versus > 9 χ^2 (1) = 7 43, significance

Discussion There was found an apparent rise in occurrence of reduced mobility with increasing age (13 – 22 – 43 per cent) This was significant when comparing the youngest with the oldest, and the middle with the oldest group An influence of age at onset of disease on the *primary* result was stated for the *late* result too

---

Influence of the primary shape of the head on the late occurrence of limitation of movement

From the histogram in *fig 9* there appeared to be a clear tendency towards good mobility in groups with primary normal and flattened ball shaped heads Among primarily irregular heads the frequency of reduced mobility increased

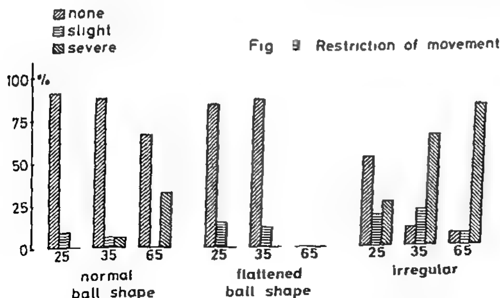

Fig 9 Restriction of movement

The figures from the histogram were tabulated in *table 20*

25 *group*	normal ball shape		flattened ball shape		irregular	
range of motion						
above 260	32	91%	33	85%	14	54%
211—260	3	9%	[illegible]	15%	5	19%
below 210	0	0	0	[illegible]	7	27%
	35		39		26	

Table 20 A Mobility related to primary shape
Statistics Normal versus flattened ball shape No significance Flattened versus irregular χ^2 (1) = 7.37 significance Normal ball shape versus irregular χ^2 (1) = 11.36 high significance

35 *group*						
above 260	14	88%	7	88%	1	11%
211—260	1	6%	1	12%	2	22%
below 210	1	6%	0		6	67%
	16		8		9	

Table 20 B Mobility related to primary shape
Statistics Numbers of patients very small Normal versus flattened ball shape No significance Flattened versus irregular χ^2 (1) = 9 91 significance Normal ball shape versus irregular χ^2 (1) = 14.00 high significance

65 *group*						
above 260	2	67%			1	7 5%
211—260	0				1	7,5%
below 210	1	33%			11	85 0%
	3				[illegible]	

Table 20 C Mobility related to primary shape
Statistics Very small numbers of patients Ball shape versus irregular χ^2 (1) = 5.56 possible significance

Further statistical calculations were made in the vertical columns in table 20 A to 20 [illegible], concerning changes in mobility between the age of 25 to that of 35

Normal shapes no significance

Flattened shapes no significance

Irregular [illegible] group versus irregular 35 group χ^2 (1) = 4 98, possible significance

Discussion No difference could be demonstrated in mobility between normal and flattened ball shaped heads In the 25 group as well as in the 35 group irregular heads showed a significantly higher frequency of limitation of movement, compared to normal and flattened ball shaped heads

Among normal and flattened ball shapes no changes were traced from the age of 25 to that of 35 On the contrary, the irregular heads showed a possible significant increase in limitation of mobility during that decade

Secondary mobility compared to secondary radiological *coxarthrosis* (table 21) and to *pain* (table 22)

Mobility	> 260		211—260		< 210	
no radiological arthrosis	82	80%	12	69%	1	4%
slight	19	18%	5	26%	8	30%
severe	2	2%	1	5%	18	66%
total 149	103		19		27	

Table 21 Secondary mobility related to radiological arthrosis Three cases refused x ray examination
Statistics Criterias of classification χ^2 (4) = 85 46 $p < 0.001$ No independance between the two criterias of classification

Influence of age at onset of LCPD on the late occurrence of limitation of movement, was shown in *table 19*

Age at onset age group	≦ 4 25+35		65	5—8 25+35		65	≧ 9 25+35		65
above 260	33	87%	1	52	78%	3	16	57%	0
211—260	4	11%	0	10	15%	1	4	14%	1
below 210	1	2%	4	5	7%	3	8	29%	6
	38		4	67		7	28		7

Table 19 Restriction of movement arranged according to age at onset of LCPD and age group at follow up examination

Statistics The 25 *and* 35 *groups combined The* 65 *group was inserted for comparison Slight and severe added*

< 4 versus 5—8 No significance

5—8 versus > 9 χ^2 *(1) = 4 06 possible significance*

< 4 versus > 9 χ^2 *(1) = 7 43 significance*

Discussion There was found an apparent rise in occurrence of reduced mobility with increasing age (13 – 22 – 43 per cent) This was significant when comparing the youngest with the oldest, and the middle with the oldest group An influence of age at onset of disease on the *primary* result was stated for the *late* result too

Influence of the primary shape of the head on the late occurrence of limitation of movement

From the histogram in *fig 9* there appeared to be a clear tendency towards good mobility in groups with primary normal and flattened ball shaped heads Among primarily irregular heads the frequency of reduced mobility increased

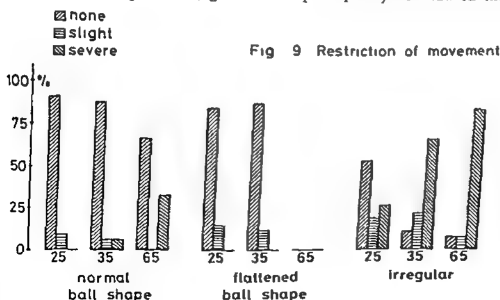

Fig 9 Restriction of movement

Present Study

An attempt was made to code the present cases into a scheme for functional capacity like that of Danielsson However, nearly all cases fell into the best groups with an absence of overflow to other groups, which made statistical comparisons impossible

For that reason it was attempted to extract the walking ability alone It was arranged in *three groups* according to a procedure of estimation resembling that for pain and mobility

Discussion The results of this study were so close to the findings concerning radiological coxarthrosis, pain and mobility that it was found needless to repeat the same conclusions regarding on the one hand walking disability, and on the other 1) lack of treatment (65 group) 2) high age group at commencement of treatment, 3) primary shape of the head, and 4) severe secondary radiological coxarthrosis

Social conditions

A brief history of social and allied conditions was taken in all cases They could be outlined in a scheme as follows

	25		35		65	
Taken the hip condition into account in choice of occupation	33	33%	5	15%	2	11%
later change in occupation	8	8%	4	12%	5	26%
applied for rehabilitat on	21	21%	6	18%	1	5%
obtained disablement pension	1	1%	(1)		5	26%

Table 23 Social conditions One case in 35 group received pension for causes other than LCPD

Discussion Differences between the groups were merely an expression for their different possibilities, according to changes and improvements in social legislation Allotment of pension and change in occupation was more frequent among the 65 group, whereas the younger groups had the opportunity to be helped in choice of occupation or for rehabilitation measures

Rejection for military service was stated in the following manner

Age group	25		35		65	
number of men	76		28		14	
rejection	57	75%	17	61%	[illegible]	71%

Table 24 Military service

Discussion Rejection must depend on traditions as the frequency of non fitness for service in the young groups far exceeded that of signs and symptoms for disablement

Finally questions were asked as to whether the patients from the 25 and 35 groups called to mind their prolonged stay in hospital as disagreeable

Age group		≦ 4		5—8		≧ 9	
all cases treated with bed rest	133	38	29%	67	50%	28	21%
recalled hospital stay as disagreeable	17	4	24%	8	47%	5	29%

Table 25

Discussion 13 per cent (17 out of 133 patients) recollected their hospital stay as disagreeable One case recalled that it *was disagreeable* to come home

The 17 cases were distributed on the age groups approximately as the age groups on the whole material

Mobility	> 260		211—260		< 210	
no pain	83	79%	6	30%	3	11%
slight pain	16	15%	11	55%	8	31%
severe pain	6	6%	3	15%	16	59%
total 152	105		20		27	

Table 22 Secondary mobility related to secondary pain

Statistics: Criterias of classification χ^2 (4) = 69 5, $p < 0\,001$ No independance between the two criterias of classification

Discussion: There was found to be good correlation between on the one side mobility, and on the other side, radiological coxarthrosis and on pain at the follow up examination

Atrophy

Present Study

Atrophy was measured in centimetres at the level of the distal belly of the vastus medialis Differences above 2 centimetres were registered at the follow up examination in the **25**-group in 18 cases (18 per cent), in the **35**-group in 5 cases (15 per cent) and in the **65**-group in 13 cases (68 per cent)

Within each of the three age groups the occurrence of atrophy at the follow up examination was compared to the primary shape and to the secondary occurrence of radiological coxarthrosis, pain and mobility

In the **25**-group atrophy was related to the primary occurrence of deformed heads (flattened ball shape + irregular heads) with possible significance

Likewise the **25**-group showed accordance between secondary atrophy and secondary walking difficulties (possible signifiance)

For both the **35**- and the **65**-groups no statistical significant correlation of these parameters could be demonstrated Nor was atrophy in the **25**-group statistically correllated to any other parameters than the above mentioned

Discussion The **25**- and **35**-groups were both treated with bed rest followed by a period of walking with crutches and the diseased leg bound up in a Snyders sling It might have been expected that this terminal treatment had resulted in a severe and long standing atrophy This was not the case In the two young groups atrophy occurred with equal frequency (18 and 15 per cent respectively), whereas the untreated group showed 68 per cent atrophy It seems, thus, to be the degree of deformity and of coxarthrosis that determine the atrophy rather than the treatment

In the **25**-group, atrophy was correlated to primary shape of the head This finding was not repeated in the other groups, possibly caused by the small numbers in these samples

Functional capacity and ability to walk

Literature

Sundt (1949) mentioned 'lameness and limping in 31 cases among 149 examined for this matter In the rest of the cases impairment of functional capacity was imperceptible

Danielsson (1964) used the walking distance together with other parameters in an accumulated index for functional capacity This index was set up for the assessment of severe coxarthrosis in old age groups

Present Study

An attempt was made to code the present cases into a scheme for functional capacity like that of Danielsson However, nearly all cases fell into the best groups with an absence of overflow to other groups, which made statistical comparisons impossible

For that reason it was attempted to extract the walking ability alone It was arranged in *three groups* according to a procedure of estimation resembling that for pain and mobility

Discussion The results of this study were so close to the findings concerning radiological coxarthrosis pain and mobility that it was found needless to repeat the same conclusions regarding on the one hand walking disability, and on the other 1) lack of treatment (65 group), 2) high age group at commencement of treatment 3) primary shape of the head, and 4) severe secondary radiological coxarthrosis

Social conditions

A brief history of social and allied conditions was taken in all cases They could be outlined in a scheme as follows

	25		35		65	
Taken the hip condition into account in cho ce of occupation	33	33%	5	15%	2	11%
later change in occupation	8	8%	4	12%	5	26%
applied for rehabilitation	21	21%	[illegible]	18%	1	5%
obtained disablement pension	1	1%	(1)		5	26%

Table 23 Social conditions One case in 35-group received pension for causes other than LCPD

Discussion Differences between the groups were merely an expression for their different possibilities, according to changes and improvements in social legislation Allotment of pension and change in occupation was more frequent among the 65 group, whereas the younger groups had the opportunity to be helped in choice of occupation or for rehabilitation measures

Rejection for military service was stated in the following manner

Age group	25		35		65	
number of men	76		28		14	
rejection	57	75%	17	61%	10	71%

Table 24 Military service

Discussion Rejection must depend on traditions as the frequency of non fitness for service in the young groups far exceeded that of signs and symptoms for disablement

Finally questions were asked as to whether the patients from the **25**- and **35** groups called to mind their prolonged stay in hospital as disagreeable

Age group		≤ 4		5—8		≥ 9	
all cases treated with bed rest	133	38	29%	67	50%	28	21%
recalled hospital stay as disagreeable	17	4	24%	8	47%	5	29%

Table 25

Discussion 13 per cent (17 out of 133 patients) recollected their hospital stay as disagreeable One case recalled that it was disagreeable to come home

The 17 cases were distributed on the age groups approximately as the age groups on the whole material

Mobility	> 260		211—260		< 210	
no pain	83	79%	[illegible]	30%	3	11%
slight pain	16	15%	11	55%	8	31%
severe pain	[illegible]	6%	3	15%	16	59%
total 152	105		20		27	

Table 22 Secondary mobility related to secondary pain

Statistics Criterias of classification χ^2 (4) = 69 5 $p < 0.001$ No independance between the two criterias of classification

Discussion There was found to be good correlation between on the one side mobility, and on the other side, radiological coxarthrosis and on pain at the follow up examination

Atrophy

Present Study

Atrophy was measured in centimetres at the level of the distal belly of the vastus medialis Differences above 2 centimetres were registered at the follow up examination in the **25**-group in 18 cases (18 per cent), in the **35**-group in 5 cases (15 per cent) and in the **65**-group in 13 cases (68 per cent)

Within each of the three age groups the occurrence of atrophy at the follow up examination was compared to the primary shape and to the secondary occurrence of radiological coxarthrosis, pain and mobility

In the **25**-group atrophy was related to the primary occurrence of deformed heads (*flattened ball shape + irregular heads*) with possible significance

Likewise the **25**-group showed accordance between secondary *atrophy and secondary* walking difficulties (possible signifiance)

For both the **35**- and the **65**-groups no statistical significant correlation of these parameters could be demonstrated Nor was atrophy in the **25**-group statistically correllated to any other parameters than the above mentioned

Discussion The **25**- and **35**-groups were both treated with bed rest followed by a period of walking with crutches and the diseased leg bound up in a Snyders sling It might have been expected that this terminal treatment had resulted in [illegible] severe and long standing atrophy This was not the case In the two young groups atrophy occurred with equal frequency (18 and 15 per cent respectively), whereas the untreated group showed 68 per cent atrophy It seems, thus, to be the degree of deformity and of coxarthrosis that determine the atrophy rather than the treatment

In the **25**-group, atrophy was correlated *to primary shape of the head This finding was not repeated in the other groups*, possibly caused by the small numbers in these samples

Functional capacity and ability to walk

Literature

Sundt (1949) mentioned lameness and limping in 31 cases among 149 examined for this matter *In the rest of the cases* impairment of functional capacity was imperceptible

Danielsson (1964) *used the walking distance together with other parameters in* an accumulated index for functional capacity This index was set up for the assessment of severe coxarthrosis in old age groups

flattened ball shaped heads had, up to the present examination of the samples, the same good prognosis as had the normal ball shapes

b) irregular shapes had a very high frequency of secondary troubles

10 The above statement (9 a) might be explained by the fact that primarily 'ball shaped heads', according to the present definitions and methods turn to 'normal ball shape' during growth from primary healing up to adult age (Tab 1)

11 The clinical examination of mobility showed that

a) rotations were the characteristic and first direction of movement to be reduced

b) atrophy was rare in the young groups even if they had been finally treated with a period of weight bearing on one leg Atrophy was frequent in the 65-group with its high incidence of irregular heads with coxarthrosis

12 Treatment The primarily untreated 65 group showed a significantly higher frequency of severe coxarthrosis and late troubles than did the 25- and 35 groups, that were consistently relieved from weight bearing during the active phases of the disease

GENERAL CONCLUSIONS

The present three samples of LCPD were reexamined at a mean of 25 and 35 years (primarily treated) and 65 years (untreated) of age

The two former samples were comparable concerning composition of *sex* and *stage* at time of diagnosis

A slight difference in *age* at onset of treatment was eliminated by combining the two groups in the comparisons

The following could be concluded

1 At 25 as well as 35 years of age a very low frequency of severe radiological coxarthrosis was found (less than 6 per cent) (Tab 2)

2 The 65-group was untreated It comprised a very high percentage of irregularely healed heads The frequency of severe radiological coxarthrosis was above 85 per cent

3 At 25 and 35 years of age the occurrence of radiological coxarthrosis was nearly equal, as regards the whole group (Tab 2)

Regarding only the irregularly healed heads in the same two groups, a 'possible significant' rise in occurrence of coxarth rosis was demonstrated during the decade from 25 to 35 years (Tab 6)

4 Severe pain was recalled to have started partly from the time of primary healing (before the age of 10), partly during the decades from 20 to 40 years of age (Tab 14)

The irregularly healed heads showed a 'possibly significant' rise in occurrence of pain from the age of 25 to 35 (Tab 12)

Thus, the '*secondary* coxarthrosis' arose 20 to 30 years before the pain at '*primary* coxarthrosis', according to the statements of Ruelle

5 A few normal (and flattened) ball shaped cases complain of pain (tab 12) and show slight restriction of mobility (Tab 20)

This may be due to chance However, possibly other unknown factors than purely mechanical may play a role in the development of disablement in a few cases Slight fissures in the cartilage are supposed to give rise to the beginning of coxarthrosis Such slight fissures might be supposed to be the result of the primary deformation in some cases

6 *Sex* played no role for the late clinical or radiological result in the present samples

7 The *stage* at onset of treatment gave no reflection on the late results

8 *Age* of the child at establishment of diagnosis and treatment had a significant influence on late occurrence of radiological coxarthrosis pain and mobility

The younger the patients the better the late results

9 *Primary shape* of the head had a significant influence on the late occurrence of radiological coxarthrosis, pain and mobility

a) primary normal versus flattened ball shaped heads showed no significant difference in late complications Thus,

INTRODUCTION

Skeletal muscles are composed of muscle fibres with differing speed of contraction, fibre diameter, and metabolism. *Slow* contracting fibres have a higher activity of oxidative enzymes but usually a smaller diameter than *fast* contracting fibres (Eccles *et al.*, 1958, Dubowitz & Pearse, 1960). Most muscles contain both slow and fast fibres, and it has been suggested that the amount of each type of fibres is related to the anatomical position and the functional utilization of each muscle. Anti gravitation muscles, which are situated deep within a muscle group, have a higher percentage of slow fibres than superficially located muscles. This interrelationship has been found in several laboratory animals (Ariano *et al.*, 1973) as well as in man (Edgerton *et al.*, 1975).

The maximal blood flow capacity is 2-3 times higher in slow muscles (e.g. the soleus) than in fast muscles (e.g. the gastrocnemius) (for a review see Hudlická (1973)). While the arrangement of large intramuscular vessels (Spalteholz, 1888, Hammersen, 1964) and the amount of vessel anastomoses (Saunders *et al.*, 1957, Stingl, 1973) seem to be similar in the two types of muscles, the capillary network is denser in slow muscles than in fast muscles (Ranvier, 1874, Romanul, 1965, Cotter, 1975). Differences in blood-flow characteristics and reactive hyperaemia have also been suggested (Gray, 1971, Burton & Johnson, 1972).

Endurance exercise increases the muscle fibre diameter but also the activity of oxidative enzymes in the fibres (Holloszy *et al.*, 1971). The number of capillaries is enhanced parallel to the fibre hypertrophy but there is no change in the number of capillaries per mm^2 of muscle tissue (Hermansen & Wachtlová, 1971).

REVIEW OF THE LITERATURE

CLASSIFICATION OF MUSCLE FIBRES

Skeletal muscles were first distinguished by their differences in pigmentation and content of lipid droplets, as *white* and *red* (see review by Close, 1972). The white muscles are *fast* contracting while the red are *slow* contracting, as shown e.g. by Denny-Brown (1929). Histochemical analyses of the enzyme activity in muscle fibres have later revealed that most skeletal muscles contain three separate types of fibres.

Table 1

CLASSIFICATION OF MUSCLE FIBRES

	Fast twitching		Slow twitching
Dubowitz & Pearse (1960)	II	(II)	I
Brooke & Kaiser (1970)	IIB	IIA	I
Henneman & Olson (1965)	A	B	C
Burke *et al.* (1971)	FF	FR	S[1]
Peter *et al.* (1972)	FG	FOG	SO[2]
	(white)	(red)	(red/intermediate)

[1] FF = fast-fatigable, FR = fast-resistant to fatigue, S = slow-very resistant to fatigue.
[2] FG = fast-glycolytic, FOG = fast-oxidative-glycolytic; SO = slow-oxidative.

Originally, these types of fibres were called white, intermediate and red (e.g. Ogata, 1958) When it was found that only the intermediate fibres have a slow contraction pattern, the terminology was revised to fast-twitch white, slow-twitch intermediate and fast-twitch red (Barnard *et al* , 1971).

In clinical practice, fast and slow contracting muscle fibres have usually been recognized as type II and type I respectively (Table 1). Subgroups of type

The motor neurons are assumed to have some "trophic" influence on the muscle fibre metabolism (Guth, 1968). If the motor nerves to a "slow" and to a "fast" muscle are sectioned and then resutured in *reversed* position ("cross,innervation"), a parallel change of the fibre metabolism and the capillary density will follow (Romanul & Pollock, 1969). Similarly, the number of capillaries and the oxidative capacity of "fast" muscles will be increased when the intact motor nerve is intermittently stimulated for more than 4 days, with an impulse frequency naturally occurring in the nerves to "slow" muscles (Pette *et al.*, 1973; Brown *et al.*, 1976). This method of intensifying the muscle activity *is usually referred to as "chronic" or "long-term"* stimulation. In contrast to muscle exercise, it does *not cause fibre hypertrophy, but there is still an* increased capillary density. Furthermore, the chronically stimulated "fast" muscle gains several features characteristic of a "slow" muscle (Hudlická *et al.*, 1977).

It has been questioned whether the vascular architecture and the muscle fibre population is different in very thin and extended muscles as compared to thicker, polygonal or fusiformed muscles. Doubts have also been raised concerning the existence of actual capillary growth in muscles subjected to chronic stimulation. These problems will be elucidated in the present investigation, which deals with angiographic, intravital microscopic and histochemical analyses of the relationship between the peripheral vascular bed and the fibre population in hind limb muscles.

ical identification via PAS-staining in combination with e g., staining for SDH activity (Table 2). With this technique it has been shown that muscle fibres belonging to the same motor unit are histochemically identical (Edstrom & Kugelberg, 1968, Burke & Tsairis, 1973). The motor units vary in their speed of contraction and their sensitivity to fatigue, and Burke *et al* (1971,1973) therefore described the three categories of muscle fibres as fast contracting - fast fatigable, fast contracting - resistant to fatigue, and slow contracting - very resistant to fatigue (Table 1) These terms were considered to be less confusing as compared to "white and red" fibres (since both of these types of fibres are fast contracting) and to "type II and type I" or "A, B, C" fibres (since this nomenclature is also used for nerve fibres).

Peter *et al* (1972) quantified the glycogen concentration and the activity of several enzymes in muscles dominated by a single type of muscle fibres. It was suggested that the fast-twitch white fibres (the nomenclature by Barnard *et al* , 1971) should be called *fast-twitch-glycolytic, FG*, since they were found to have a very high anaerobic capacity (high glycogen concentration and high activity of glycolytic enzymes) and a low aerobic capacity (low cytochrome concentration and SDH activity). The fast-twitch red fibres were found to have a moderate to high anaerobic as well as high aerobic capacity (very high cytochrome concentration and SDH activity) and they were therefore called *fast-twitch-oxidative-glycolytic, FOG* The slow-twitch intermediate fibres had a low anaerobic and a moderate to high aerobic capacity and the name *slow-twitch-oxidative, SO*, was suggested (see Tables 1, and 2).

Some investigators have also described subgroups of FG and FOG fibres (Romanul, 1964, Schmalbruch & Kamieniecka, 1975) and of SO fibres (Askanas & Engel, 1975). These findings might be due to individual enzyme activities in muscle fibres belonging to the same type of fibres (cf. Nolte & Pette, 1972).

II fibres (II A and II B) were described by Brooke & Kaiser (1970) from studies of the actomyosin ATPase activity at various pH levels (Table 2).

A third system of nomenclature has been used by e.g. Henneman & Olson (1965) and Kugelberg & Edström (1968), by which the white, red and intermediate fibres are called A, B, and C, respectively. These terms might, however, cause confusion since other investigators (e.g. Stein & Padykula, 1962) designate intermediate fibres as B and red fibres as C.

Repetitive stimulation of the muscle fibres innervated by a single motor neuron will result in depletion of the glycogen content in these muscle fibres. The whole motor unit is then accessible for histochem-

Table 2

HISTOCHEMICAL STAINING INTENSITY AND METABOLISM OF MUSCLE FIBRES

Enzymes		FG	FOG	SO
SDH[1]				
$NADH_2$ - diaphorase[2]				
Mitochondrial α-GPDH[3]				
PAS[4]				
ATPase[5]	pH 9 4			
	pH 4 7			
Metabolic capacity	aerobic	low	high	moderate / high
	anaerobic	very high	moderate / high	low

[1] SDH = succinate dehydrogenase
[2] $NADH_2$ - diaphorase is oxidizing the co-enzyme NADH2 (nicotinamide-adenine dinucleotide) to NAD
[3] GPDH = glycerophosphate dehydrogenase
[4] PAS = periodic acid - Schiff test (for glycogen content)
[5] ATPase = adenine triphosphatase.

ical identification via PAS-staining in combination with e g., staining for SDH activity (Table 2). With this technique it has been shown that muscle fibres belonging to the same motor unit are histochemically identical (Edström & Kugelberg, 1968, Burke & Tsairis, 1973) The motor units vary in their speed of contraction and their sensitivity to fatigue, and Burke *et al* (1971,1973) therefore described the three categories of muscle fibres as fast contracting - fast *fatigable*, fast contracting - *resistant* to fatigue, and slow contracting - very resistant to fatigue (Table 1) These terms were considered to be less confusing as compared to "white and red" fibres (since both of these types of fibres are fast contracting) and to "type II and type I" or "A, B, C" fibres (since this nomenclature is also used for nerve fibres)

Peter *et al* (1972) quantified the glycogen concentration and the activity of several enzymes in muscles dominated by a single type of muscle fibres It was suggested that the fast-twitch white fibres (the nomenclature by Barnard *et al* , 1971) should be called *fast-twitch-glycolytic, FG*, since they were found to have a very high anaerobic capacity (high glycogen concentration and high activity of glycolytic enzymes) and a low aerobic capacity (low cytochrome concentration and SDH activity) The fast-twitch red fibres were found to have a moderate to high anaerobic as well as high aerobic capacity (very high cytochrome concentration and SDH activity) and they were therefore called *fast-twitch-oxidative-glycolytic, FOG* The slow-twitch intermediate fibres had a low anaerobic and a moderate to high aerobic capacity and the name *slow-twitch-oxidative, SO*, was suggested (see Tables 1, and 2)

Some investigators have also described subgroups of FG and FOG fibres (Romanul, 1964; Schmalbruch & Kamieniecka, 1975) and of SO fibres (Askanas & Engel, 1975) These findings might be due to individual enzyme activities in muscle fibres belonging to the same type of fibres (cf Nolte & Pette, 1972)

VASCULAR ARCHITECTURE AND CAPILLARY DENSITY IN SKELETAL MUSCLE TISSUE

Qualitative studies of injection specimens have revealed a *primary* and a *secondary* anastomosing vascular network, at the pre-capillary level, in skeletal muscles (Spalteholz, 1888; Krogh, 1922; Hammersen, 1964; Stingl, 1969). It was also stated by Spalteholz (1888) that most muscles contain numerous anastomoses. Campbell & Pennefather (1919) postulated three different groups of muscles in man, according to the number of afferent muscle arteries and the pattern of intramuscular arterial anastomoses. Classification of muscles in man has also been based on the vascular arrangement, together with the anatomical and functional features of the examined muscles (Saunders *et al.*, 1957). From investigations of muscles in various animal species, Stingl (1973) emphasized that the pattern of vascular anastomoses is the optimal criterion for grouping of muscles with different vascular architecture. Neither the review of the literature nor the observations in the study by Stingl revealed any correlation between the pre-capillary vascular arrangement and the fibre content in the examined muscles.

However, several investigators have found that muscles dominated by FG fibres contain few, straight capillaries, while muscles rich in SO fibres have numerous, wide and "sinusoidal" capillaries (Ranvier, *1874; Stoel, 1925; Lee, 1958; Romanul*, 1965).

Attempts have been made to quantify *the number of capillaries per mm^2 of muscle tissue* (see Hudlická, 1973). The calculations were usually performed on cross-sections from muscles subjected to vascular perfusion of India ink. The numbers of capillaries/mm^2 show a considerable divergence, which is usually interpreted to be a result of species differences but mainly caused by tissue shrinkage artefacts and unequivalent diameter of the FG, FOG, and SO fibres (see Table 2).

The number of capillaries per muscle fibre (also called *capillary/fibre ratio*) is independent of the tissue dimensions and therefore considered to be more representative for the capillary density. Data of this type have also confirmed the difference in capillarization found by Ranvier (1874) and other investigators (see also review by Hudlická, 1973).

From histochemical staining of the capillary endothelium, Romanul (1965) observed that the number of capillaries surrounding each muscle fibre was directly proportionate to the activity of oxidative enzymes in the fibres. Plyley & Groom (1975) found no difference in the capillarization of muscle fibres with respect to the fibre metabolism. In fact, they stated that "any differences in capillary density are primarily a consequence of differences in mean fiber size".

AIMS OF THE PRESENT INVESTIGATION

1) To test the representativeness of the tenuissimus muscle for skeletal muscle tissue in general, concerning the vascular architecture and the capillary supply of the muscle fibres. The thin cat tenuissimus was compared with thicker hind limb muscles of the cat (the dorsal part of the biceps femoris, the gastrocnemius - both heads separately - and the soleus) in the following respects
   a muscle anatomy and vascular architecture (I),
   b. evaluation of the muscle fibre population and the capillary supply of fibres with differing diameter and metabolism (II)
2) To develop a method suitable for intravital studies of skeletal muscles subjected to various levels of activity The rat extensor hallucis proprius (EHP) was selected as experimental muscle (III).
3) To quantify the total capillary surface area and search for direct evidence of growing capillaries in chronically stimulated rabbit tenuissimus and rat EHP muscles (IV).

METHODOLOGICAL CONSIDERATIONS

GENERAL

Combined structural and functional studies have been found necessary for analyses of the regulatory mechanisms involved in the blood flow distribution in skeletal muscle. This type of experimental approach is possible by intravital microscopy, but these *in situ* observations with transmitted light are limited to thin muscles (III).

The vasculature of thicker muscles can be analysed in injection specimens. With radiographic technique it is possible to visualize the whole vascular tree, and even extramuscular vessels (cf. Saunders *et al.*, 1957). The main disadvantage of this method is the poor resolution of the microvascular bed, even if radiopaque injectants with minimal particle size and viscosity are used. The microvessels can, however, be studied satisfactorily after Indian ink perfusion and clarifying of the muscle according to the method of Spalteholz (1888, 1911; see also Romeis, 1948). A certain degree of tissue shrinkage is unavoidable and to reach the deeper parts of the muscle belly, the specimens have to be sectioned. From consecutive serial sections it is possible to reconstruct the whole intramuscular vessel tree with reasonable accuracy.

Measurements of vessel dimensions can be carried out during intravital microscopy. With controlled physiological conditions these figures would also be representative, since the vascular tone is preserved (cf. Baez, 1969; Eriksson, 1972).

For quantification of the capillary density in skeletal muscle tissue, conventional histological technique with formalin fixation should be avoided because of the tissue shrinkage artefacts. Dye perfusion of the vascular bed is also unreliable, since filling of the capillary network is usually incomplete (cf. Plyley and Groom, 1975; see also Hudlická, 1973).

A preferable method is freeze fixation, cryostat sectioning and histochemical staining for alkaline phosphatase activity (Gomori, 1939, Pearse, 1968) This enables specific identification of the endothelium in all capillaries present in the section, with the degree of tissue shrinkage kept to a minimum

Correlation of the capillary density to the muscle fibre population is important for a complete understanding of the nutritional characteristics of skeletal muscle tissue Various methods for histochemical staining of the enzyme activities in muscle fibres have been described (see review by Khan, 1976) With this technique it has been possible to evaluate the capacity of glycolytic, oxidative and lipolytic enzymes in different muscle fibres Quantification of the cross-sectional area or mean diameter of the fibres can also be performed (cf Edström and Torlegaard, 1968/69 Cotter *et al*, 1973) since the linear dimensions of the tissue are fairly well preserved with careful freeze fixation

The fibre mass of skeletal muscles is grouped in fibre bundles (Figs 1 and 5) As a constant pattern most of the large glycolytic FG fibres are located close to the border of this bundle Thus, evaluation

Fig 1 Muscle fibre bundle (indicated by arrows) in the biceps femoris Corss section histochemically stained for the activity of alkaline ATPase according to the method described by Padykula & Herman (1955)

METHODOLOGICAL CONSIDERATIONS

GENERAL

Combined structural and functional studies have been found necessary for analyses of the regulatory mechanisms involved in the blood flow distribution in skeletal muscle. This type of experimental approach is possible by intravital microscopy, but these *in situ* observations with transmitted light are limited to thin muscles (III).

The vasculature of thicker muscles can be analysed in injection specimens. With radiographic technique it is possible to visualize the whole vascular tree, and even extramuscular vessels (cf. Saunders *et al.*, 1957). The main disadvantage of this method is the poor resolution of the microvascular bed, even if radiopaque injectants with minimal particle size and viscosity are used. The microvessels can, however, be studied satisfactorily after Indian ink perfusion and clarifying of the muscle according to the method of Spalteholz (1888, 1911; see also Romeis, 1948). A certain degree of tissue shrinkage is unavoidable and to reach the deeper parts of the muscle belly, the specimens have to be sectioned. From consecutive serial sections it is possible to reconstruct the whole intramuscular vessel tree with reasonable accuracy.

Measurements of vessel dimensions can be carried out during intravital microscopy. With controlled physiological conditions these figures would also be representative, since the vascular tone is preserved (cf. Baez, 1969; Eriksson, 1972).

For quantification of the capillary density in skeletal muscle tissue, conventional histological technique with formalin fixation should be avoided because of the tissue shrinkage artefacts. Dye perfusion of the vascular bed is also unreliable, since filling of the capillary network is usually incomplete (cf. Plyley and Groom, 1975, see also Hudlická, 1973).

After the perfusion, all animals were divided at the lumbo-sacral level. The skin was stripped off from the hind part of the body, which was then fixed in 10% buffered formalin for 7 days. Serial sections, 500 µm thick, were cut (perpendicularly and longitudinally to the direction of the muscle fibres) from the proximal, the central and the distal part of each examined muscle (I). The tenuissimus muscles (IV) were thin enough to be examined without sectioning.

After preparation of the muscle specimens (ad modum Spalteholz), the distinctly delineated vessel tree could be analysed in a 3-D microscope. Comparative measurements of the vascular segments were carried out with an optical micrometer By using a phase contrast condenser in a Leitz Orthoplan microscope, it was also possible to study the connective tissue around different parts of the vessel tree (I).

The arrangement of large nutritive vessels to the muscle belly (I) was studied by radiography after intravascular perfusion of 500 ml of a 50% saline suspension of barium sulphate (0.4 g/ml, Mixobar[R], Astra, Sweden).

HISTOCHEMISTRY

Fixation of the muscle specimens was performed in propane-propene (II), and in isopentane which was cooled in liquid N_2 (III and IV) Serial sections, 7-10 µm thick, were cut in a cryostat, perpendicularly to the direction of the muscle fibres For qualitative fibre differentiation, the sections were stained histochemically for the activity of $NADH_2$-diaphorase (Chayen *et al* , 1973) and alkaline (pH 9.4) actomyosin ATPase (Padykula and Herman, 1955). In some experiments (III), the sections were stained for the activity of SDH (Nachlas *et al* , 1957) instead of $NADH_2$-diaphorase. Both of these methods demonstrate the oxidative capacity of the individual muscle fibres (Khan, 1976).

of the percentage of different types of muscle fibre as well as the number of capillaries per fibre should be based on entire muscle fibre bundles. Randomized fields of the histological cross-section would be difficult to standardize and would most likely be less representative for the total fibre population.

MATERIALS AND ANAESTHESIA

The cats (in I and II) were of both sexes and weighed about 2.5 kg. During the experiments they were anaesthetized with i.v. injections of chloralose (50 mg/kg) after induction with ether.

The analyses of chronically stimulated tenuissimus muscles (IV) were performed on New Zealand Red rabbits of both sexes, weighing 1.7-2.5 kg. For implantation of electrodes they were anaesthetized with thiopentone sodium (100 mg/kg, i.v.) and during intravital microscopy (after terminated stimulation) with pentobarbitone sodium (30 mg/kg, i.v.).

Female Wistar rats, weighing 130-150 g, were used in III and IV. These animals were anaesthetized with ether during the implantation of electrodes. When they were subjected to intravital microscopy the anaesthesia was initiated with 1.5 mg of diazepam and then completed with pentobarbitone sodium (3-4 mg/100 g body weight), intraperitoneally.

ANGIOGRAPHY

Via a cannula in the abdominal aorta, the hind limbs of cats and rabbits were perfused with 500 ml of Indian ink, diluted with saline 1:1, after pre-perfusion with 300 ml of Perfadex[R] (Pharmacia, Sweden). Papaverine (0.2 mg/kg) was added to induce maximal vasodilatation and the perfusion pressure was 13.3 kPa (100 mmHg). The purpose of the pre-perfusion was to wash out blood cells and plasma as far as possible. Ink particles have been found to form aggregates in contact with plasma proteins (Brånemark *et al.*, 1968), and any such aggregates would interfere with the filling of the microvessels.

rabbits the venous blood pressure was measured via a cannula in the small saphenous vein

The peripheral vascular bed was studied *in vivo* (III, and IV) using Leitz Intravital microscopes (Biomed and Large model, Leitz-Wetzlar, W Germany The Large microscope was modified for high resolution recordings by Lab Exp Biology Göteborg)

Objectives (UO x11, NA 0 25, UO x23, NA 0 55, UO x55, NA 0 84) giving a magnification of up to x660 were used A heat-absorbing green filter (maximal transmission at 5500 Å) was used to minimize the influence of light on the tissue during the observation period

Recordings of the terminal arterioles, the capillary bed and the collecting venules were made with the microscope connected to a closed circuit TV system with a video tape recorder (see IV) Photographic registrations were made on Kodak Monochrome film (SO 410) with a Leitz System camera in the Biomed microscope and a Nikon F camera (Nippon Kogaku, Japan) in the Large microscope Additional cinematographic documentation was performed in the Large microscope (see IV)

EVALUATION OF FIBRE POPULATIONS AND THE CAPILLARY BED

From each series of muscle sections, 10 entire muscle fibre bundles were analysed (see I) This corresponds to about 400 muscle fibres By comparing photographs from serial sections, alternatively stained for the activity of $NADH_2$-diaphorase (or SDH) and alkaline actomyosin ATPase different fibre types (FG,FOG,SO or A,B C) could be distinguished and quantified Fibre diameters were calculated by taking the mean of 4 polygonal diameter measurements, on each of the studied fibres, in calibrated photographs (Cotter *et al* , 1973)

The number of capillaries/muscle fibre in 20 adjacent fibre bundles (approximately 6000 μm^2 in rat EHP) was calculated in each series of sections The number of capillaries surrounding each individual muscle fibre was also registered in II, while the number of capillaries per mm^2 of muscle tissue was calculated for evalu-

The capillaries were visualized by a modified Gomori (1939) method for alkaline phosphatase (IV) and by the method of unspecific alkaline ATPase, as described by Guth and Samaha (1969,1970) - II, III, and IV.

CHRONIC MUSCLE STIMULATION

Rabbit tenuissimus and rat EHP muscles were chronically stimulated for [illegible] h/day during 6-14 days (IV).

Stainless steel electrodes were implanted, under aseptic conditions, in the vicinity of the common peroneal nerve in rats. To avoid extensive surgery of the tenuissimus muscles (supplied by a deep branch of the sciatic nerve), the electrodes were implanted onto the distal end of the muscle (about 2 cm distal to the area of intravital microscopy). The wires, led subcutaneously to emerge through the back of the animals, were connected by a flexible lead to conventional stimulators (Grass S8, and SD9). During stimulation (square wave pulses, duration 0.3 msec, frequency 10 Hz)* the animals were allowed to move freely in their cages (cf. Salmons and Vrbová, 1969; Pette *et al.*, 1973; Brown *et al.*, 1976). The stimulation intensity (usually 3-6 V) was adjusted to evoke maximal contraction of the muscles, but it was kept low enough to avoid discomfort to the animals.

For control of the operation trauma, one group of rabbits were sham-operated (electrodes were implanted without subsequent stimulation). In rats the contralateral intact and unstimulated muscle served as control, while in rabbits the control muscles had to be taken from different animals to the stimulated ones.

INTRAVITAL MICROSCOPY

The animals were breathing spontaneously via a tracheal cannula. One of the carotid arteries was cannulated for continuous monitoring of the arterial blood pressure (transducer, Statham; pen recorder, Devices). In

*Close to the normal discharge frequency for motor neurons innervating slow muscles (Eccles *et al.*, 1958).

rabbits the venous blood pressure was measured via a cannula in the small saphenous vein.

The peripheral vascular bed was studied *in vivo* (III, and IV) using Leitz Intravital microscopes (Biomed and Large model, Leitz-Wetzlar, W. Germany. The Large microscope was modified for high resolution recordings by Lab. Exp. Biology, Goteborg).

Objectives (UO x11, NA 0.25; UO x23, NA 0.55; UO x55, NA 0.84) giving a magnification of up to x660 were used. A heat-absorbing green filter (maximal transmission at 5500 Å) was used to minimize the influence of light on the tissue during the observation period.

Recordings of the terminal arterioles, the capillary bed, and the collecting venules were made with the microscope connected to a closed circuit TV system with a video tape recorder (see IV). Photographic registrations were made on Kodak Monochrome film (SO 410) with a Leitz System camera in the Biomed microscope and a Nikon F camera (Nippon Kogaku, Japan) in the Large microscope. Additional cinematographic documentation was performed in the Large microscope (see IV).

EVALUATION OF FIBRE POPULATIONS AND THE CAPILLARY BED

From each series of muscle sections, 10 entire muscle fibre bundles were analysed (see I). This corresponds to about 400 muscle fibres. By comparing photographs from serial sections, alternatively stained for the activity of $NADH_2$-diaphorase (or SDH) and alkaline actomyosin ATPase, different fibre types (FG,FOG,SO or A,B,C) could be distinguished and quantified. Fibre diameters were calculated by taking the mean of 4 polygonal diameter measurements, on each of the studied fibres, in calibrated photographs (Cotter *et al.*, 1973).

The number of capillaries/muscle fibre in 20 adjacent fibre bundles (approximately 6000 μm^2 in rat EHP) was calculated in each series of sections. The number of capillaries surrounding each individual muscle fibre was also registered in II, while the number of capillaries per mm^2 of muscle tissue was calculated for evalu-

ation of the total capillary surface area (TCSA) in III and IV.

During analyses of the video tape recordings, obtained from intravital microscopy, the monitored image was projected onto the focusing glass of a camera obscura. This gave a final magnification of about 3000 times. The architecture of the microvascular tree was registered and the vessel dimensions were measured with a microgauge.

The length of each capillary was measured from the point of which it branched off from the obliquely running terminal arteriole and downstream to its connection with another capillary to form an obliquely running collecting venule. The internal capillary diameter was measured at both the arteriolar and the venular end of individual capillaries.

Capillary surface area in rat muscles (III, and IV) was calculated using a combination of the data obtained from the *in vivo* observations (the dimensions of individual capillaries) and the histochemical analyses (capillary counts and total muscle dimension).

RESULTS AND COMMENTS

COMPARATIVE ANALYSES OF THE TENUISSIMUS AND THICKER HIND LIMB MUSCLES OF THE CAT

Anatomy of the muscles studied

The tenuissimus (also called abductor cruris caudalis; Crouch, 1969) is 12 - 14 cm long and about 0.4 cm wide. It is a quadrilateral muscle, only 0.1 - 0.6 mm thick (see Eriksson & Myrhage, 1972), and has a wet weight approximately 0.25 g. Originating on the coccygeal vertebra, the muscle runs on the medial side of the biceps femoris, close to its dorsal edge (Fig. 2), and inserts on the flat tendon of the biceps as well as in the crural fascia. The muscle fibres, which are only 2 cm long and therefore interdigitated (Adrian, 1925) are oriented parallel to the longitudinal axis of the muscle.

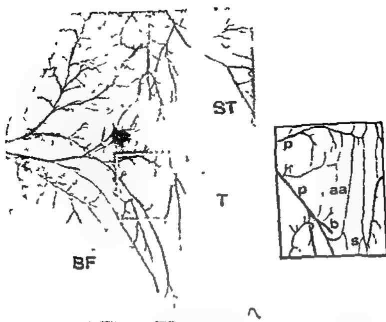

Fig. 2. The biceps *femoris* muscle (BF). The tenuissimus (T) is slightly dislocated in the *dorsal direction*. *ST* is the semitendinosus muscle. Two *primary* arteries (p) are connected by an *arterio-arterial anastomosis* (aa), which is a little wider than the *secondary* artery (s). One of the primary arteries has a branch (b) which during the dissection was found to penetrate the muscle fascia into the subcutaneous tissue and the skin. Full scale radiograph.

The biceps femoris covers most of the lateral surface of the thigh. This muscle is trilateral and considerably thicker than the tenuissimus. The dorsal third of this muscle is distinctly thinner than the rest of the muscle belly. This dorsal part of the muscle might be equal to the small head, but in the literature on cat anatomy the two heads are usually not defined (cf. Crouch, 1969). The dorsal part, which can be separated by blunt dissection, has a wet weight of about 3.2 g. The biceps muscle originates from the tuberosity of the isciadic bone and inserts on the lateral margin of the patella and the proximal third of the tibia. The muscle fibres are oriented parallel to the longitudinal axis of the muscle.

The lateral head of the gastrocnemius (LG) actually consists of three fusiformed beelies converging into a common sheet of the Achilles tendon. Each belly has a separate origin; the small lateral one originates from the deep side of the biceps tendon, the central one from a sesamoid bone (fabella) on the dorsal side of the lateral condyle of the femur and the medial belly originates from the proximal part of the plantaris muscle. Furthermore, the medial belly is fused (deep distally) with the plantaris muscle and (superficially) with the medial head of the gastrocnemius.

The medial head of the gastrocnemius (MG) is a fairly flat muscle with a delicate origin on the medial fabella and the adjacent part of the medial condyle of the femur. The insertion tendon is fused with the LG tendon. These tendons together comprise the superficial part of the Achilles tendon, covering the insertion of the plantaris and the soleus muscles.

The MG has a wet weight of about 7.4 g (the corresponding figure for the LG is 7.6). The muscle fibres of the LG are oriented parallel to the longitudinal axis of the muscle, while the MG fibres are attached to the dorsal muscle fascia and pass obliquely down to the ventral fascia.

The soleus has a long fleshy origin on the lateral side of the proximal third of the fibula and inserts into the deep portion of the Achilles tendon. The wet weight of this muscle is about 1.9 g. The muscle fibres pass from the muscle origin obliquely down to the dorsal muscle fascia.

Arrangement of the vascular tree (I)

The tenuissimus muscle contains one "central" artery (about 70 µm in diameter) and one or two "central" veins (diam., 90 µm). This group of vessels runs parallel to the orientation of the muscle fibres, and usually has an uninterrupted course through the muscle. *Terminal* arterioles (20 µm) and venules (40 µm) branch off from the central vessels in a two-dimensional pattern (Fig. 3a). These vessels run transversely or

Fig 3 a) Spalteholz preparation of the tenuissimus muscle showing the "central" artery and vein (c) and transverse (terminal) arterioles and venules (t) A terminal venule (tv) runs close to the muscle fascia The vascular network (v) supplies fascia-embedded adipose tissue
b) Longitudinal section of the LG muscle, prepared ad modum Spalteholz Obliquely running *primary* vessels (p) subdivide into *secondary* vessels (s), which give rise to terminal arterioles and venules (t)

obliquely to the muscle fibres and are in the periphery subdivided into capillaries which are oriented parallel to the direction of the muscle fibres.

The central vessels of the tenuissimus correspond directly to the *secondary* generation of branches from the large intramuscular vessels in the biceps femoris (Fig. 2), the LG (Fig. 3b) and the MG as well as the soleus muscle.

In these muscles the supplying arteries subdivide into a *primary* generation of branches (Fig. 2). These vessels had a similar diameter range, 150-350 µm. The *secondary* arteries of thicker muscles were slightly wider (60-100 µm) than the corresponding vessels of the tenuissimus. The endpoints of the *primary* arteries were interconnected by *arterio-arterial anastomoses*, slightly wider (80-150 µm) than the *secondary* vessels (Fig.2).

Terminal arterioles branche off from the *arterio-arterial anastomoses* as well as the *secondary* arteries in a three-dimensional pattern. The diameter range of the *terminal* arterioles was 25-40 µm, i.e. they were a little wider than in the tenuissimus.

The primary as well as the secondary veins follow the course of the corresponding arteries. Duplicated *primary veins* are common only in the soleus muscle, while duplicated *secondary veins* occur both in the soleus and in the MG muscles.

Terminal venules running close to the muscle fascia were found frequently in the tenuissimus muscle (Fig. 3a). Such vessels were also found in the other muscles, especially in the MG.

The average distance between secondary vessels was 1600-1800 µm in the biceps and the LG muscles, about 1200 µm in the MG, and 800-900 µm in the soleus. The cross-sectional area of the tissue cylinder (Fig. 4) supplied by one secondary artery in the MG muscle is about 1 mm^2. This value is in the range of the total cross-sectional area of the tenuissimus.

Arterio-venous anastomoses were not observed at any level within the muscles examined. This finding is in accordance with observations by Hammersen (1968). In the tenuissimus muscle, however, several of the terminal vessels penetrate the epimysium and enter the surrounding connective tissue. This type of vascular communication was also found in the other muscles, e.g. in the biceps and the soleus, where some primary vessels penetrated the muscle fascia and supplied the subcutaneous tissue and the skin (Fig. 2).

Both the tenuissimus and the biceps contain several anastomoses between the endpoints of the primary vessels. This is a common feature of flat and extended muscles (Stingl, 1973). These anastomoses were less frequent in the LG muscle. In the MG and the soleus, anastomoses were only seen connecting the largest of the primary vessel branches.

The present investigation shows that *the vascular arrangement found in the tenuissimus muscle exists as a "basic unit" in thicker muscles* (Fig. 4) The terminal arterioles and venules, which branch off from the secondary vessels in a three-dimensional pattern (two-dimensional in the tenuissimus), supply a cylinder of muscle fibres.

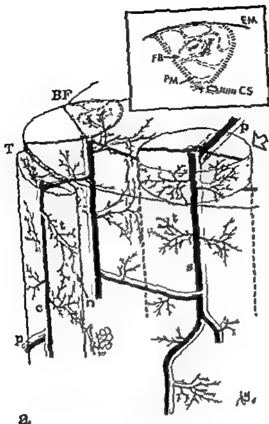

Fig 4 a) The vascular arrangement of the tenuissimus muscle (*T*) is found as a "basic unit" in thicker muscles (here represented by the biceps femoris, BF) The terminal arterioles and venules (t) of this vascular basic unit are supplying the capillary network within a cylinder of muscle tissue (indicated by open arrow). p= primary-, c= "central"- and s= secondary vessels; n= capillary network *The fibre mass is first grouped by connective tissue* septa (CS) and then subgrouped by two levels of perimysium (PM), enclosing the fibre bundles (FB) EM= epimysium.
b) Cross-section of the biceps muscle, clarified *ad modum* Spalteholz - conventional condenser c) Phase *contrast condenser.*

Such cylinders in the MG muscle have an average cross-sectional area which corresponds fairly well to the total area of a cross-section through the tenuissimus.

Types of muscle fibres and capillary supply (II)

Freezing in liquid propane-propene preserves the skeletal muscle with a minimum of tissue artefacts. Serial cryostat cross-sections stained alternately for $NADH_2$- diaphorase and alkaline ATPase permit a qualitative classification of types of muscle fibre (Fig. 5).

The nomenclature used by Burke *et al* (1971) merely describes the functional characteristics of the muscle fibres (Table 1). The functional properties in relation to the histochemical staining pattern of individual motor units have been described in detail for the cat gastrocnemius muscle (Burke & Tsairis, 1973, Burke *et al.*, 1973). It would therefore seem reasonable

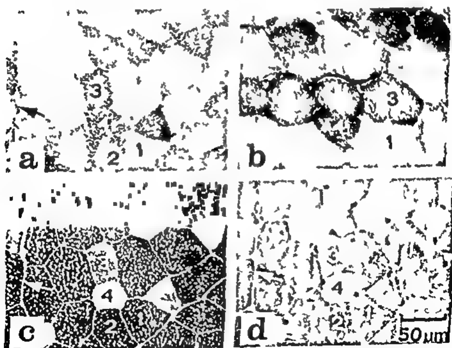

Fig 5 Cryostat sections of the LG (a, c, and d) and of the MG muscle (b) Histochemical staining for $NADH_2$-diaphorase activity (a, and b) and alkaline ATPase activity, ad modum Padykula & Herman (c), and Guth & Samaha (d), respectively 1 = FG, 2 = FG/FOG, 3 = FOG, 4 = SO Arrows indicate the border-line of a muscle fibre bundle

to use the more explicit nomenclature of Peter *et al* (1972), which also indicates the metabolic capacity of each type of fibres The fast contracting fibres are either mainly glycolytic (FG) or both glycolytic and oxidative (FOG), and the slow contracting fibres are mainly oxidative (SO)

In accordance with the findings of Ariano *et al* (1973), the biceps femoris and the LG muscles were found to be dominated by FG fibres (40-50% of the total fibre population) The major part of all muscles in this study had a higher percentage of FOG fibres than was reported by Ariano This discrepancy might be due to different levels of exercise of the investigated animals, since endurance training is known to increase the number of FOG fibres (Barnard *et al* , 1970, Jansson & Kaiser, 1977) In the present study the highest number of FOG fibres was found in the tenuissimus muscle (45-50% of the fibres) The MG muscles had about 35% of SO fibres, twice as much as the LG, biceps femoris and tenuissimus The soleus consisted to almost 100% of SO fibres

Some fibres with high alkaline ATPase activity (which is typical for FG fibres) had a $NADH_2$-activity corresponding to the FOG fibres This intermediate type of fibre, called FG/FOG fibres, generally formed 10-15% of the fibre populations in the biceps femoris and the LG muscles A similar fibre type has been found in cat LG and tibialis anterior muscles by Hammarberg (1974)

The MG and the soleus generally had larger fibres than the other muscles (Fig 5) The average fibre diameter reflects the contractile force of the muscle, but is also influenced by the muscle fibre orientation. In the MG and the soleus, both ends of all fibres are attached to the epimysium (Burke & Tsairis, 1973, Murphy & Beardsley, 1974) Sections of these muscles, perpendicular to the fibres, thus contain few fibres which are cut close to the fibre endpoint The other muscles have fibres oriented parallel to the longi-

tudinal axis of the muscle, the length of which exceeds the fibre length. Consequently, these fibres are interdigitated and several of them will be cut close to the fibre end points in a muscle cross-section. This would explain the low values of average fibre diameter found especially in the tenuissimus.

The soleus muscles contained quite large SO fibres. In the other three muscles studied, this type of fibre had a smaller average diameter than the fast contracting fibres. The FG fibres were the largest fibres in all evaluated muscles, with the exception of the soleus which did not contain these fibres (Fig. 6).

Endothelial cells have a high alkaline phosphatase activity (Gomori, 1939; Romanul, 1965). According to e.g. Freiman & Kaplan (1960), this enzyme is capable of hydrolyzing ATP, which is used as substrate in histochemical staining of ATPase activity. In the present investigation the alkaline ATPase activity was examined with a histochemical method containing no blocking agent for alkaline phosphatase (Guth & Samaha, 1969; 1970). This enabled quantification of the different types of muscle fibres as well as the total number of capillaries in the same tissue section.

Romanul (1965) suggested that the number of capillaries around each muscle fibre is directly correlated to the oxidative capacity of the muscle fibres. It has later been stated that the fibre diameter is the only factor determining the capillarization of muscle fibres. The present calculations revealed a fairly linear relationship between fibre size and number of fibre-surrounding capillaries for all types of muscle fibres. However, the large FG fibres were surrounded by fewer capillaries than the smaller FOG and SO fibres (Fig.6). The values of capillaries around fibres were lower in all the biceps femoris and the LG muscles studied as compared to the tenuissimus muscles, which in turn had lower values than the MG and the soleus muscles. This difference in capillarization was confirmed by calculations of the capillary/muscle-fibre ratio.

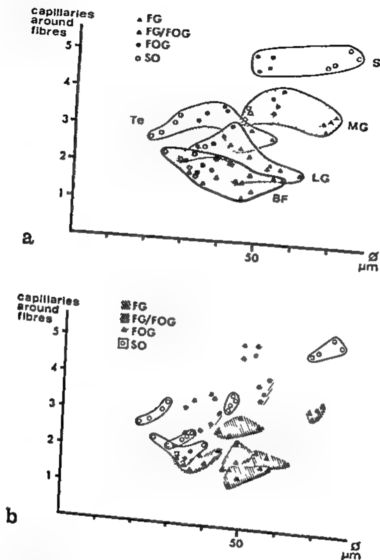

Fig 6 The average number of capillaries around individual muscle fibres, in relation to fibre type and average diameter of the fibres (in four animals) a) values grouped for different muscles, b) values grouped for different fibre types. Te = the tenuissimus muscle, BF = the biceps femoris, LG = the lateral head and MG = the medial head of the gastrocnemius, S = the soleus

tudinal axis of the muscle, the length of which exceeds the fibre length. Consequently, these fibres are interdigitated and several of them will be cut close to the fibre end points in a muscle cross-section. This would explain the low values of average fibre diameter found especially in the tenuissimus.

The soleus muscles contained quite large SO fibres. In the other three muscles studied, this type of fibre had a smaller average diameter than the fast contracting fibres. The FG fibres were the largest fibres in all evaluated muscles, with the exception of the soleus which did not contain these fibres (Fig. 6).

Endothelial cells have a high alkaline phosphatase activity (Gomori, 1939; Romanul, 1965). According to e.g. Freiman & Kaplan (1960), this enzyme is capable of hydrolyzing ATP, which is used as substrate in histochemical staining of ATPase activity. In the present investigation the alkaline ATPase activity was examined with a histochemical method containing no blocking agent for alkaline phosphatase (Guth & Samaha, 1969; 1970). This enabled quantification of the different types of muscle fibres as well as the total number of capillaries in the same tissue section.

Romanul (1965) suggested that the number of capillaries around each muscle fibre is directly correlated to the oxidative capacity of the muscle fibres. It has later been stated that the fibre diameter is the only factor determining the capillarization of muscle fibres. The present calculations revealed a fairly linear relationship between fibre size and number of fibre-surrounding capillaries for all types of muscle fibres. However, the large FG fibres were surrounded by fewer capillaries than the smaller FOG and SO fibres (Fig.6). The values of capillaries around fibres were lower in all the biceps femoris and the LG muscles studied as compared to the tenuissimus muscles, which in turn had lower values than the MG and the soleus muscles. This difference in capillarization was confirmed by calculations of the capillary/muscle-fibre ratio.

The EHP muscle is supplied by three small branches from the anterior tibial artery. Most of the veins leave the proximal part of the muscle to the anterior tibial vein. However, three to four veins (30-50 µm in diameter) drain the distal part of the muscle to the deep fascia and into the tendon. Usually, the EHP contains one central artery, about 30 µm in diameter and running parallel to the longitudinal axis of the muscle. Proximally, this vessel is accompanied by a vein (about 40 µm in diameter), which distally is a fusion of venous branches running close to the margins of the muscle. Terminal arterioles and venules branch off in a pattern similar to that in the tenuissimus (Eriksson & Myrhage, 1972). The capillaries have a few intercapillary branches. The capillary blood-flow is intermittent, with periods of varying flow and periods (10-60 sec.) of circulatory arrest (cf. Burton & Johnsson, 1972). The average internal diameter of the capillaries is 4.0 µm at the arteriolar end and 5.5 µm close to the collecting venule. Measured from the branching off from the terminal arteriole down to the collecting venule, the average capillary length is 535 µm.

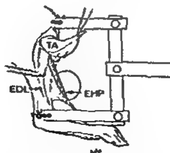

Fig 7 The EHP muscle exposed for intravital microscopy. The lower leg of the rat is stabilized with a holder and the EHP muscle, with intact deep fascia, is placed on a glass cone and transilluminated. Both of the adjacent muscles (extensor digitorum longus, EDL, and the tibialis anterior, TA) are gently held aside

Thus *the capillary supply of muscle fibres seems to be directly proportional to the oxidative enzyme activity as well as the diameter of individual muscle fibres.* The thin tenuissimus muscle does not differ from thicker muscles in this respect. The comparably large number of capillaries in relation to the average fibre diameter in the tenuissimus can reasonably be explained by the high proportion of FOG fibres in this muscle.

THE EXTENSOR HALLUCIS PROPRIUS MUSCLE (EHP) OF THE RAT (III).

There seems to be no major discrepancies between the tenuissimus and thicker hind limb muscles of the cat as regards the architecture of the vascular bed and the capillary supply of the muscle fibres. However, considering the point of insertion in relation to the knee joint, it is questionable whether the tenuissimus muscle acts primarily as a muscle of locomotion.

Only the marginal parts of thick, fusiformed or polygonal muscles that are of importance for locmotion can be used for *in vivo* observations of skeletal muscle circulation (see Gray, 1971). In the case of the fusiformed EHP muscle of adult rats, even the belly is thin enough to be transilluminated for intravital microscopy.

From its origin on the central part of the fibula and the interosseous membrane, the EHP muscle runs parallel to the extensor digitorum longus on the deep side of the tibialis anterior muscle. The tendons of the EHP and latter muscle pass together under the transverse crural ligament, whereafter the EHP tendon follows the medial side of the paw and inserts on the second phalanx of the first digit. By dividing the ligament and the tendon of the tibialis anterior muscle, the EHP can be held out ventrally and exposed for intravital microscopy (Fig. 7). The major part of the vascular bed can be analysed with an adequate resolution.

physiological characteristics of the nerve innervating the muscle is indicated from experiments on "cross-innervation" (Romanul & Pollock, 1969).

Chronic stimulation, at a low impulse frequency, of the intact nerve to a fast muscle has a slowing effect on the speed of contraction. Simultaneously the glycolytic enzyme activity decreases while the glucose phosphorylation and the fatty acid activation increase This is later followed by an increased oxidative capacity (Pette *et al* , 1973). After 28 days of stimulation the histochemical fibre staining pattern in the fast muscle can not be distinguished from that of a slow muscle (Brown *et al* , 1976)

In the chronically stimulated rat EHP muscle, the percentage of glycolytic fibres (FG) decreased steadily with the time of stimulation Parallel to this, there was an increase in the number of oxidative fibres (SO and FOG), which showed a slightly intesified staining for SDH activity as compared to the corresponding fibres in the control muscles The average diameter of FG fibres was smaller after stimulation, while the dimensions of SO and FOG fibres were not changed (Fig. 8) This is in accordance with observations from stimulated large rabbit muscles (Cotter *et al* , 1973)

In vivo observations of the microvascular bed in stimulated muscles revealed an increased internal diameter of the capillaries This was most prominent in the tenuissimus muscles stimulated for 7 days, where the average capillary diameter was 6 1 um at the arteriolar and 9 5 um at the venular end of the capillary as compared to 4 7 and 6 1 um, respectively, in the control animals It should be emphasized that these figures represent relative values But the differencies are real since the measurement error is the same.

In the stimulated EHP muscles the increase in diameter of the capillaries was smaller, but still detectable by the simple fact that the erythrocytes did not deform to the same extent during passage through

The muscle fibre mass of the EHP is dominated by fast glycolytic (FG) fibres (about 60%, average diameter: 35 μm). Slow oxidative fibres (SO) constitute 15-20% (diam. about 20 μm) and the rest of the fibres are of the FOG type (diam. 25-30 μm).

The proximal cross-section of the muscle contains on average 1350 capillaries/mm^2, and close to the tendon the value is about 1050. The discrepancy might be explained by the decreased dimension of the muscle fibres as they insert into the tendon.

The total capillary surface area (TCSA), as calculated from *in vivo* measurements of individual capillaries and histochemical data on capillary density and related to the total dimensions of the muscle, amounts to an average value of 1.6 m^2/100 g of muscle tissue. A considerably lower value of TCSA (0.7) was found by Pappenheimer *et al.* (1951) in India-ink-perfused cat muscles. Species differences, e.g. differing body size, might explain this discrepancy (Schmidt-Nielsen & Pennycuik, 1961). It should be noted, however, that evaluations of capillary density from injection specimens may easily underestimate the total number of capillaries, since it is difficult to fill all capillaries present in the tissue with this technique.

The anatomy and the location of the EHP muscle is quite favourable for structural and functional *in vivo* analyses of the skeletal muscle circulation. Being a well-defined locomotor muscle with a proper tendon, the *EHP would be more suitable than the tenuissimus for studies of tissue nutritional adaptation to various levels of muscle activity.*

CHRONIC STIMULATION OF THE RABBIT TENUISSIMUS AND THE RAT EHP MUSCLES (IV).

Postnatal differentiation of the muscle fibre metabolism and the vascular bed in skeletal muscles is closely connected with the functional activity of the muscles (Hudlická, 1973). A direct correlation between the fibre metabolism, the capillary density, and the

Recent fusion of two sprouts was indicated by hourglass-shaped capillary segments Erythrocytes were frequently observed being very slowly squeezed through these narrow passages A similar pattern of capillary growth has been described for the tadpole tail (Meyer, 1853), the rabbit ear chamber (Clark & Clark, 1939, Cliff, 1963, Brånemark, 1965, Lindhe & Brånemark, 1970) and for healing muscle wounds (Schoefl, 1963; McKinney & Panner, 1972) The proportion of sprouts to preexisting capillaries was about 40% in both the tenuissimus and the EHP muscles after 14 days of stimulation This figure corresponds roughly to the values of increased capillary density found in stimulated rabbit muscles (Cotter *et al* , 1973, Brown *et al.*, 1976)

The newly formed capillaries often had a winding or tortuous appearance, similar to the capillaries normally found in slow muscles (Romanul, 1965).

The total capillary surface area (TCSA) had an average value of 1 41 m^2/100 g of muscle tissue in the contralateral control muscles This value was in-

Neither *the diameter* nor the metabolism of the muscle fibres, not even the capillary/fibre ratio are changed in fast contracting muscles subjected to chronic stimulation at an impulse frequency *exceeding* 10 Hz. Similarly, no changes in the fibre population or the capillary/fibre ratio of slow contracting muscles, were found after chronic stimulation at 40 Hz - the impulse frequency normally occurring in nerves to fast muscles - (Brown *et al.*, 1976).

It should be noted, however, that in the case of chronic stimulation an altered pattern of activity is *superimposed* on the normal motor nerve activity. In "cross-innervation" the *total* activity of the motor nerve is altered, which actually changes the metabolism and the number of capillaries even in slow contracting muscles (Romanul & Pollock, 1969).

In view of this, the pattern of activity in the motor nerve seems to be more important than the level of muscle exercise as a regulating factor for the metabolism and the *capillary supply* of muscle fibres.

COMMENTS ON VASCULAR INTERCONNECTIONS BETWEEN SKELETAL MUSCLES AND OTHER MESENCHYMAL TISSUES

The main trunks of about 30% of the "transverse" arterioles and venules regularly penetrate the fascia of the tenuissimus muscle and ramify into the deep extended part of the fascia (Fig. 7). These vessels form a capillary network supplying the adipose tissue, which is embedded in the fascia (cf. Myrhage *et al.*, 1973)

Similarly, 4-5 branches of primary arteries and veins were found to leave the belly of all examined biceps femoris muscles. Careful dissection revealed that these vessels subdivided in the subcutaneous tissue adjacent to the muscle. Such interconnecting vessels were also observed in the LG and the MG muscles, where they, however, are smaller and less frequent.

creased by 29% (1.81) in muscles stimulated for 7 days and by 46% (2.08) in muscles stimulated for 14 days.

Factors connected with tissue injury, e.g. granulocyte-released substances (Brånemark, 1965) and histamine (Smith, 1961; Schoefl, 1963), have been suggested as initiating capillary growth during tissue regeneration. In the chronically stimulated muscles this type of stimulus is probably not present, since histological examinations showed no signs of inflammation and mast cells were only occasionally observed in close vicinity to the sprouts. Furthermore, there was no change in capillary diameter and no capillary sprouts in the sham-operated tenuissimus muscles.

Collagen, which has been observed close to the tip of capillary sprouts, might support the growth of new capillary segments (Cliff, 1963; McKinney & Panner, 1972). In the stimulated muscles, we frequently found a bright, wedge-like zone around the tip of the sprouts. The location of this zone corresponds well to the site of the collagen fibres in the previous studies.

It has been postulated by Ashton (1961), that endothelial cells are directly sensitive to oxygen and start multiplying at low oxygen levels. A high capillary density has also been found in animals living continuously at high altitudes (Valdivia, 1958). Increased muscle activity, by prolonged contractions at 10 Hz, seems to be associated with a considerable increase in oxygen consumption (Cotter & Hudlická, unpublished data). Thus, it cannot be excluded that chronic stimulation causes a relative hypoxia in the muscle during the first few days of stimulation, which might provoke the gradual increase in TCSA.

Endurance muscle training increases the diameter of the muscle fibres parallel to the number of capillaries per fibre (Hermansen & Wachtlova, 1971). In contrast to this, the muscle fibres have a smaller average diameter after chronic stimulation at 10 Hz but still an increased capillary/fibre ratio.

evaluated as the number of fibre surrounding capillaries and as the number of capillaries per muscle fibre.

A method was developed for intravital microscopy and estimation of the total capillary surface area (TCSA) of the rat extensor hallucis proprius muscle (EHP).

Blood flow distribution in the microvascular bed, the structure of the capillary network, and changes in TCSA were evaluated in chronically stimulated, adult rabbit tenuissimus and rat EHP muscles.

From the results the following conclusions are made:

1. A vessel arrangement, similar to that found in tenuissimus, is present as a "basic unit" even in the thicker hind limb muscles.
2. The average cross-sectional area of this unit in the MG muscle is in the range of the total cross-sectional area of the tenuissimus (about 1 mm^2). This value is about 80% greater in the biceps femoris and the LG muscles, but 50% less in the soleus.
3. Generally, all fibres in the MG are 20-40% larger than the corresponding fibres in the tenuissimus, the biceps and the LG. The soleus has quite large SO fibres (about 70 µm in diameter) as compared to this type of fibre (25-45 µm) in the other muscles.
4. Cat muscles with large muscle fibres have a higher number of capillaries per fibre (1-2) than muscles with a smaller average fibre diameter (relative value, less than 1 capillary). In spite of a larger diameter, the FG fibres are surrounded by fewer capillaries (1-3) as compared to the FOG, and the SO fibres (2-4). It seems most likely that the oxidative capacity of the fibre is more important than the fibre diameter as a regulatory factor for the fibre capillarization.

The main trunk of a primary artery penetrated the distal part of the soleus in about 75% of all the examined muscles. This vessel (followed by two parallel primary vein branches) ramifies in the crural fascia and also gives branches to the periosteum of the tibia.

Corresponding vascular interconnections have also been found in the lower leg of man (Saunders *et al.*, 1957). From investigations of injured rabbit EHP muscles, Zucman (1960) concluded that intact vascular anastomoses between muscle and periosteum are essential for successful revascularization of the muscle.

Thus, vascular interconnections between muscles and other mesenchymal tissues might be more important for the blood flow distribution than is generally appreciated.

Intravital microscopy has been found quite suitable for investigations of these vascular pathways. Pilot studies of EHP muscles, subjected to various periods of denervation, indicate that vessels of this type are involved in the circulatory adaptation during muscle atrophy.

SUMMARY AND CONCLUSION

Hind limb muscles, from cats subjected to intravascular perfusion of India ink, were prepared according to the method of Spalteholz. The vascular tree in the unsectioned tenuissimus muscles was analysed and compared with the arrangement of vessels in sectioned, thicker hind limb muscles (the biceps femoris, the gastrocnemius - both heads, separately, and the soleus).

Quantification of different fibre types (FG, FOG, and SO) was performed in serial cryostat sections, histochemically stained for the activity of $NADH_2$-diaphorase (or SDH) and alkaline ATPase. The capillary endothelium was identified by staining for the activity of alkaline phosphatase, and the capillary density was

evaluated as the number of fibre surrounding capillaries and as the number of capillaries per muscle fibre

A method was developed for intravital microscopy and estimation of the total capillary surface area (TCSA) of the rat extensor hallucis proprius muscle (EHP)

Blood flow distribution in the microvascular bed, the structure of the capillary network, and changes in TCSA were evaluated in chronically stimulated, adult rabbit tenuissimus and rat EHP muscles.

From the results the following conclusions are made

1 A vessel arrangement, similar to that found in tenuissimus, is present as a "basic unit" even in the thicker hind limb muscles

2 The average cross-sectional area of this unit in the MG muscle is in the range of the total cross-sectional area of the tenuissimus (about 1 mm^2) This value is about 80% greater in the biceps femoris and the LG muscles, but 50% less in the soleus

3 Generally, all fibres in the MG are 20-40% larger than the corresponding fibres in the tenuissimus, the biceps and the LG The soleus has quite large SO fibres (about 70 µm in diameter) as compared to this type of fibre (25-45 µm) in the other muscles.

4 Cat muscles with large muscle fibres have a higher number of capillaries per fibre (1-2) than muscles with a smaller average fibre diameter (relative value, less than 1 capillary) In spite of a larger diameter, the FG fibres are surrounded by fewer capillaries (1-3) as compared to the FOG, and the SO fibres (2 4) It seems most likely that the oxidative capacity of the fibre is more important than the fibre diameter as a regulatory factor for the fibre capillarization

5. The tenuissimus muscle does not differ from thicker muscles in respect of the vascular arrangement and the capillary supply of muscle fibres, although the tenuissimus seems to be of minor importance for locomotion.

6. The rat EHP is a typical locomotor muscle and is also quite suitable for combined intravital and histochemical studies. FG fibres dominate in this muscle. The vascular bed has an arrangement similar to that of the tenuissimus. However, the capillaries have fewer interconnections, which is in advantage for evaluations of the TCSA.

7. Chronic muscle stimulation of fast contracting muscles at 10 Hz results in widening of the capillaries, especially close to the collecting venules. The capillary density is also increased. These rearrangements of the capillary bed enhance the TCSA in the rat EHP by 46% after 14 days of stimulation.

8. Growth of new capillaries in the stimulated muscles was observed as *sprouts* emanating from pre-existing capillaries. The proportion of sprouts to preexisting capillaries is about 40% after 14 days of stimulation.

PREFACE

In 1955 Professor *E Thomasen* conceived *the idea to try* treating Legg-Calvé Perthes disease (LCPD) in a wheelchair

This idea was realized in the Orthopaedic Hospital, Århus, and in the late *1960's* *Jørgen Lauritzen* initiated a study on the results In 1967 Professor Thomasen asked me to assist Dr Lauritzen in a way so that it would be possible to compare the radiological results of wheelchair treatment with those obtained by traction in the Seaside Hospital, Refsnæs

This collaboration was the starting point of the present publication, and I am therefore *greatly indebted to Professor Thomasen* for the invitation to collaborate in the study of the wheelchair series

My collaboration with Dr Lauritzen was very successful That to me it was an inspiration is witnessed by the volume I am submitting now For the many years of good collaboration and pleasant hours spent together I am sincerely grateful

For assistance in the follow-up examinations I am indebted to *Knud Mose* M D, Physical Therapy Department, Central Hospital, Nykøbing Falster, and to Drs. *Louise Hjorth* and *Mette Ulfeldt* For help and guidance in assessing X-ray films I acknowledge my indebtedness to *Marcus Schalimtzek* M D, *Erik Rostgaard Christensen* M D, and *Ellen Jensen*, M D, Radiology Department, Orthopaedic Hospital, Copenhagen, as well as to *Henrik Schiøler*, M D, Radiology Department, Rigshospitalet, University of Copenhagen

I am indebted to *Hans Bohr*, M D, Head of the Seaside Hospital, Refsnæs, for the permission to use case records for patients treated in that hospital and for the kind helpfulness with which I am invariably met by Dr Bohr and his entire staff

For the statistical calculations my thanks are due to *Jørgen Nyboe*, Head of the Statistical Department, Rigshospitalet, University of Copenhagen

This study could not have been performed or published without grants from Statens lægevidenskabelige Forskningsråd, Rigsforeningen til Gigtens Bekæmpelse, Daell Fonden, and a Foundation established by former patients in the Seaside Hospital, Refsnæs and others I wish to extend my thanks for this support

CONTENTS

INTRODUCTION

In a previous study (Meyer 1966) it was endeavoured to assess the efficacy of 4 *different methods* of treating Legg-Calvé-Perthes' disease (LCPD) Bed rest *with traction*, bed rest *without* traction, ambulatory relief from weight bearing with *Thomas' splint, no or merely symptomatic treatment*

During recent years I have also had occasion to study the efficacy of another therapeutic method – in collaboration with Jorgen Lauritzen and through the kindness of Professor E Thomasen – viz ambulatory relief from weight-bearing in *wheelchair* The results of this method were compared with those of two of the previously studied methods *Bed rest with and without traction* – the methods used by me

In the course of these investigations it was realized that the methods of assessment used in the previous study were insufficient when the treatment in wheelchair was included in the evaluation

The following principal views must be *maintained in assessing therapeutic results*

The value of any treatment must be assessed according to the *clinical* result obtained In the evaluation the share of treatment must be elucidated as far as possible, taking into consideration also the strain it has been on the patient The significance of the *radiological* result is restricted to its relation to the clinical condition

First, as regards the clinical result

A year or two after the discontinuation of treatment the radiological appearances show that after the stage of fragmentation the contours of the affected femoral head are again uninterrupted and well-defined, so that the deformity of the head, and thus also of *the hip joint, after treatment may* be assessed This time may be called the time of *primary healing* and is thus determined on the basis of the X-ray film – one might say the radiological condition

At the time of primary healing the clinical condition is practically always good The children are, broadly speaking, symptom free regardless of the treatment used

On the other hand, the *late* clinical condition, at the end of many years, is often poor, characterized by increasing osteoarthritis – *so-called secondary osteo*-arthritis – and this is the condition on which the assessment of the efficacy of treatment must be based

However, the late clinical condition cannot – at present – be directly observed *In* the most recent follow-up studies of the earliest treated materials (Heibo 1953, *Gower and Johnston* 1971, Danielsson & Hernborg 1965) the patients have reached a mean age of only about 40 The entire

rest series") they were in fact of approximately the same order of magnitude; at least thus was how they were *interpreted*. In *the other series*, which to me were "second hand", it was difficult at least to establish with certainty the stage at institution of treatment. All considered, the conclusion of the 1966 study was that the named "other factors" did not vary so widely in the series concerned that they had to be considered. Therefore, when determining the *primary deformity* of the hip joints in the various series, by the special measuring methods, it was concluded that the differences reflected the efficacy of the treatments applied. No doubt this was in the main correct with regard to the traction series and bed rest series – the two series of most interest – less correct in the others.

However, when the result of ambulatory wheelchair treatment was to be compared with those of the other therapeutic methods, it was found that the wheelchair series differed appreciably from the other series in respect to those factors which, apart from treatment, exert an essential influence upon the primary radiological deformity of the joint. The relatively simple procedure used in the study from 1966 was no longer sufficient. In the *assessment regard had to* be paid, to a much greater extent, to the influence of "other factors". This was attained by extending and supplementing the 1966 method. This, I hope, improved method was applied to the old bed rest series, *an increased traction series*, and the wheelchair series. As *might be expected*, the results found for the two previously investigated therapeutic methods were practically the same as found in 1966, only elaborated in more detail so as to permit comparison with the results of treatment in wheelchair. This elaborated method for the radiological evaluation of the therapeutic results will be described in the next sections.

The *plan* of the study to be described below was thus:

1. To give a well-defined, *quantitative description and assessment* of the nature and extent of the *radiological deformities of the joints* in the three series at primary healing. In other words, it was endeavoured to arrive at a measure of whether, and if so how much the affected hip joint differs from normal after completion of treatment.
2. To determine the *influence of the various above-mentioned factors* upon the radiological appearances, especially with *a view to isolating the role of treatment*.
3. To predict the *later clinical course* – i.e. assess the risk of osteoarthritis on the basis of the radiological appearances in the series at primary healing.

   In other words, it was endeavoured partly to determine the *relative* risk of osteoarthritis in the various series, partly the *absolute* risk of osteoarthritis in the *individual series*. The former does not pose much difficulty, but the latter certainly does. This may be stated more accurately: Deciding which degree of radiological deformity of the joint can be accepted at primary healing, if the late clinical result is to be designated good.

In particular, it was the achievement of the second item of the plan which required elaborating and supplementing the old methods. The third item – especially its *last part* – was the most difficult one and *the result least reliable*. True, this did not necessitate new methods, but a deeper probing into the *problem* was required to substantiate the reliability of the conclusion.

In carrying through the plan, all measurements were performed by *two persons*. This was done to test whether the measuring methods were applicable by two investigators, independently of each other, with *consistent results*. This is of the utmost importance with a view to com-

subsequent development of osteoarthritis – perhaps the most important part – has not been established by direct observation

But although the subsequent development of osteoarthritis has not yet been directly observed, we are not debarred from assessing the efficacy of the therapeutic methods The fact is that even at an early juncture it is possible to predict, indirectly and in broad features, the development of osteoarthritis In their follow-up studies of fairly large series int al Sundt, Helbo, and Danielsson & Hernborg arrived at the main thesis that the time of onset of secondary osteoarthritis and its severity were directly proportional to the radiological deformity of the hip joint at "primary healing" The greater the divergences from normal, the greater the risk of osteoarthritis Of course, this rule is based merely upon experience concerning the development of osteoarthritis up to the age of about 40 – but there is nothing to indicate that it could not apply also to subsequent development of osteoarthritis

Thus, if we have a method for objectively determining – measuring – the radiological deformity of the hip joint at "primary healing", it is possible to establish with reasonable certainty, already at this early juncture, whether one treatment is *more effective than the other in preventing* the occurrence of secondary osteoarthritis This means the *relative* efficacy of the methods

This method also affords some idea of the absolute, factual development of osteoarthritis in the series Those cases that have healed with practically normal femoral heads may be regarded, without major errors, as having no risk of osteoarthritis The percentage of the remaining cases then indicates the maximum possible extent of osteoarthritis in the series But this indirect method affords no concrete information about the actual time of onset of osteoarthritis, if any, its actual extent, or severity Such information is obtainable only, if it is possible to establish a definite relationship between early radiological deformities and the clinical nature of the late osteoarthritis This may be tried, but it is inevitably uncertain – and the accuracy of the result can be ascertained only by direct, late observation

The indispensable basis for any assessment of the efficacy of the various therapeutic methods, therefore, must be giving a dependable picture of the radiological deformities at primary healing in the available materials Not until then can any attempt be made to elucidate the clinical consequences of these radiological results

However, the primary deformity of a hip joint is dependent not only upon the treatment Several factors seem to be operative (Mose and others)

1 Treatment
2 Age at onset of the disease.
3 Stage of disease at institution of treatment
4 Sex

Moreover, genetic and constitutional factors must be expected to influence the result, but so far these factors are outside the scope of objective assessment In materials from a racially homogeneous population and from a geographically uniform area, however, the influence of such constitutional factors may presumably be expected to be of approximately the same extent in the various series

Then, in assessing the relative efficacy of different treatments it is not sufficient merely to determine the radiological deformity of the hip joints after completion of the treatments We must also isolate the share of treatment in the radiological result from the influence of the other factors

This problem is eliminated if the series to be assessed vary only with regard to treatment, being largely uniform as to the other factors In the 1966 study the present author determined the named factors in the different series In the series treated *with* traction and with bed rest *without* traction (called "traction series" and "bed

A RADIOLOGICAL ASSESSMENT OF THERAPEUTIC RESULTS

1 Methods of Assessment

A radiological description of articular deformities at primary healing should preferably bear the closest possible relationship to the *risk of osteoarthritis* in the series Therefore, in selecting methods of radiological description, care must always be taken that the phenomena measured really do bear relationship to the risk of osteoarthritis This risk must be included in the considerations Therefore, it is inevitable that even the radiological section should include a discussion of clinical problems A more detailed discussion of the clinical significance of the radiological results will follow in Section B

The development of deformity in the hip joint in the course of the disease is a somewhat complicated process Primarily the *epiphysis* gets deformed because of the disease process localized therein To the epiphyseal deformity the bony tissue in the metaphysis reacts by compensating growth processes trying to maintain the normal spherical shape of the femoral head (2/3 3/4 of a sphere as the joint surface normally makes up about 2/3–3/4 of a spherical surface) This may be accomplished in the mild epiphyseal deformities, but as a rule the head as a whole will get deformed In some cases it "flattens", i e the joint surfaces remain parts of a spherical surface – but only a smaller part than normal, with a longer radius. In other cases the joint surface cannot be maintained as a spherical surface, and it assumes a more irregular shape

These deformities of the head again induce reactions from the bony tissue in the *acetabular roof*, viz compensating growth processes trying to adapt the acetabular joint surface to the deformed joint surface of the head This will widely succeed – but the deformity of the head may become too marked In other words, the acetabular changes are secondary to, and vary largely in proportion to, the deformity of the head

A side effect to the severe cases of epiphyseal disease will be a reduction in the function of the epiphyseal line and thereby a reduction in the longitudinal growth of the femoral neck As the epiphyseal line of the trochanter, which looks after the longitudinal growth of the lateral part of the proximal end of the femur, is undamaged, the longitudinal growth of the entire proximal femoral end will become lopsided It remains normal laterally, but is inhibited medially This gradually leads to varus deformity of the neck Thus, a shortening and varus deformity of the neck also bear relation to the deformity of the head Shortening and varus deformity of any extent occur only in the presence of severe

paring therapeutic results obtained in different clinics and by different clinicians

It was Professor E Thomasen who suggested this testing The measurements were performed by Jorgen Lauritzen and Johannes Meyer (LAU and J M) The results will be described in a special section, supplemented by a discussion of the two investigators' somewhat divergent conclusions on the basis of the measurements (p 78)

Lauritzen reported his results in 1975 (Diss)

Total *Survey of abbreviations and symbols* fixed and defined in *the radiological section*

Abbreviations Wh = wheelchair, BR = bed rest without traction, Tr = traction in bed (often used in combinations, such as Wh series, Tr treatment, etc)

Symbols for patient groups (with features of significance in the evaluation)

A Patients arriving early for treatment, i e during the stage of condensation without flattening (initial quot >85)

B Patients arriving late for treatment i e in the stage of condensation with flattening (initial quotient ≤ 85) or in the stage of fragmentation

I Patients aged ≤ 4 years at institution of treatment

II Patients aged 5–8 years at institution of treatment

III Patients aged ≥ 9 years at institution of treatment

"SPH " Cases healed with "spherical" heads – i e heads whose surface, measured with Mose's plate, has a circular countour in 2 planes

"NORM sph " Cases healed with "spherical" heads of normal shape and size (Ep qu >60, jt surf qu >85, radius qu <115 – i e all quotients within the "normal range" cf Appendix Comment 1)

"PATH sph Cases healed with "spherical ' heads of pathological shape and/or size (at least one of the quotients outside the "normal range")

"NON sph " Cases healed with non spherical heads (without circular contour)

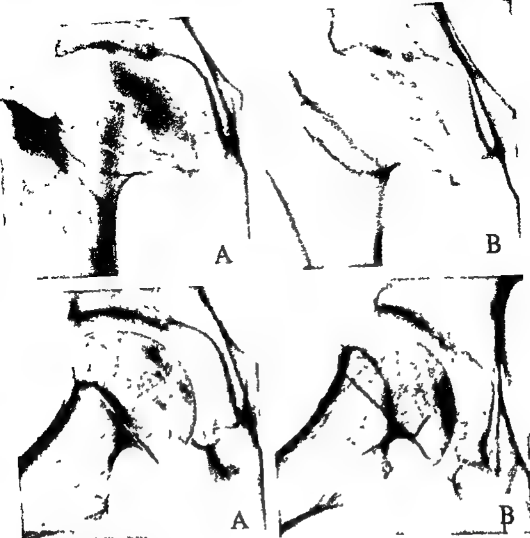

Figure 5 Two cases of right sided LCPD healed with femoral heads which though "spherical" in Mose s terminology are greatly deformed

Thus these cases belong to the group PATH sph "

shaped heads in which the contours are circular, but make up only a small part of a circle with a long radius (Fig 1)

In other words, there is a wide scope of deformities within this group which, there fore ought to be divided into a couple of smaller but well-defined groups It was attempted to attain this by picking out those cases in which the difference in shape and size between the affected and unaffected head *does not exceed that which may be observed between the right and left head in X rays of a normal pelvis* The remainder – the other group – will then *comprise cases in which the head is spher-* ical, but the difference in shape and (or) size between the affected and unaffected head is beyond what may be observed in normal persons

The former group is of importance, seeing that it may reasonably be predicted that these cases, having essentially normal

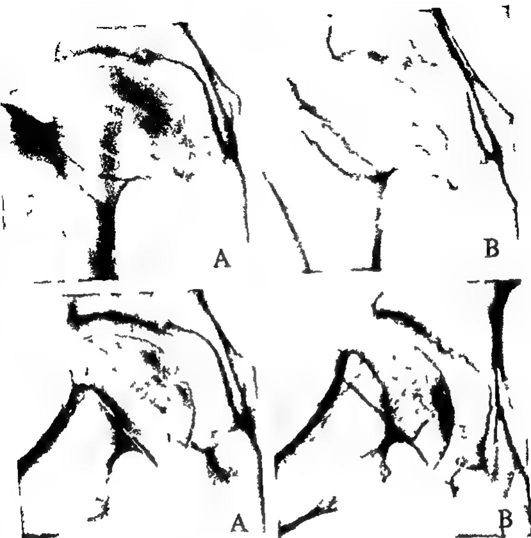
deformities of the head – e g the typical, flat "mushroom" on a short stalk

Mild subluxation of the hip joint has often been reported as being among the sequelae to LCPD In my experience, this is very uncommon At any rate it occurs, like the changes of the neck, only in the presence of very pronounced deformity of the head – and acetabulum

All considered, *the deformity of the hip joint is determined by the deformity of the femoral head* Accordingly, there is no need to perform special measurements of acetabular deformity, the position of the head in the acetabulum, or of the length and position of the neck It is fully adequate to measure only the deformity of the head when looking for information about the deformity of the hip joint as a whole

As mentioned above, the radiological deformity of the head extends over a wide range – from slight "flattening" with preserved spherical shape of the joint surface to actually angular heads A striking phenomenon, broadly speaking common to all, is *a marked increase in the growth of the head* This comprises also, though to a lesser extent, the acetabulum Unlike the shortening of the neck and the coxa vara, an increase in growth may occur also in the mildest deformities, indeed, it may be seen in some cases without deformity The affected head is merely larger than the unaffected one The role of this enlargement in the risk of osteoarthritis is difficult to estimate There is little doubt that the risk of osteoarthritis, at a given deformity of the head, will be increased when the affected head is also larger than the contralateral one, the curvature of the joint surface getting smaller The effect is accen tuated when the increase in acetabular growth is unable to keep pace with that of the head, so that the head grows too large for the acetabulum

On the whole, it may be said that a description of head deformity is incomplete without recording the attendant enlargement (Therefore, the word deformity as used below will signify deformity + enlargement, unless otherwise apparent from the context)



However, a description of the deformity of an affected head presupposes a normal head as reference, and this is available only in unilateral cases – viz the head on the unaffected side As a result, the assessment was done *only in unilateral cases* – presupposing that in bilateral cases, under the same circumstances, the hip joints are affected exactly as in unilateral cases

The determination of the radiological deformity of the femoral head was carried out as follows (For a more detailed description cf Meyer 1966)

First all bilateral cases were excluded In all the series they made up 15–17 %

Thereafter, the unilateral cases were divided into two groups (1) cases with *spherical heads,* (2) cases with *non-spherical,* "irregular" heads The distinction was done by the aid of Mose's plastic plate with scored circles A femoral head was classified as *spherical* when one of the circles covered the contours of the joint surface, in the anteroposterior as well as in Lauenstein's view (a 2 mm variation in radial length was permitted in one plane and between two planes) If this demand could not be fulfilled, the head was calssified as *non-spherical,* "irregular" This applies to large, flat heads whose contours are more curved along the edges than centrally as well as to the angular ones Within this group the deviation from normal is so great that the clinical prognosis must be definitely poor with a great risk of osteoarthritis

If only the series has been fairly well treated the group of spherical heads is a large one in which the capital shape ranges from entirely normal – like that of unaffected femoral heads – by way of somewhat "flattened" heads in which the joint surface makes up a smaller part of a sphere with a longer radius than on the unaffected side, to the greatly deformed, mushroom-

Figu e 1 Two cases of right sided LCPD healed with femoral heads wh ch though "spherical" in Mose s terminology are greatly deformed.
Thus these cases belong to the group PATH sph

shaped heads in which the contours are circular but make up only a small part of a circle with a long radius (Fig 1)

In other words there is a wide scope of deformities within this group which therefore ought to be divided into a couple of smaller but well-defined groups It was attempted to attain this by picking out those cases in which the difference in shape and size between the affected and unaffected head *does not exceed that which may be observed between the right and left head in X rays of a normal pelvis* The remainder the other group – will then comprise cases in which the head is spherical but the difference in shape and (or) size between the affected and unaffected head is beyond what may be observed in normal persons

The former group is of importance seeing that it may reasonably be predicted that these cases having essentially normal

The joint surface quotient is just above the bottom limit of the normal range

femoral heads, must have a favourable clinical prognosis, at least as compared with the other groups However, these hip joints are *not entirely* normal The affected and unaffected head are rarely exactly alike In the majority of cases there is a slight difference (but within the normal range) *In a normal* material, on the other hand, the right and left head are exactly alike in the majority of cases – deviations occurring in only a very few Perhaps, this difference between the mild capital deformities in this group and the slight physiological deviations in a normal material are not devoid of prognostic significance, but let us start by supposing that the risk of osteoarthritis in this group is *not appreciably greater than the risk of primary osteoarthritis in normal persons* (Fig 2)

In the group comprising the remaining patients with spherical heads we are dealing with real capital deformities and increases in growth considerably exceeding the modest normal variations In this group the clinical prognosis must be at least inferior to that in the 1st group

It may be said, briefly, that the 1st group comprises all cases with *normally* spherical – i e in fact *normal* – heads and the second group all cases with pathologically spherical heads Below, the former group will be abbreviated *"NORM sph"* and the latter *'PATH sph"* The third group of patients with abnormal, non-spherical heads will be designated *"NON-sph"* – and the large group with spherical heads *"SPH"*

Thus, the presupposition for dividing the "spherical" cases into two groups must be accurate methods of determining the shape and size of the spherical head

Three such methods were used Measurement of the *epiphyseal quotient joint surface quotient,* and *radius quotient*

Let it be emphasized at once that these methods are *applicable only to spherical heads* with well defined circular contours They cannot be applied to irregular or fragmented heads, as the quantities "radius of head" and "height of epiphysis", which are included in the measurements make no

ense in such cases and are therefore not measurable

A detailed description of these methods was given previously – Meyer 1966, pp 39, 42, 92, and 93, so that here it will only be briefly stated what *they mean*

The joint surface quotient is a direct expression of the shape of the affected joint surface, and thereby the affected head, in relation to the unaffected head An increase in capital size does not affect the joint surface quotient In a group of normal persons the joint surface quotient is usually *100*, but in a few cases it may be as *low as 85*

The epiphyseal quotient is a direct expression of the shape of the affected *epiphysis, i e its flattening* as compared with the unaffected one (but not as stringently stereometrically as the joint surface quotient expresses *the shape of the joint surface*) *Increased* growth of the epiphysis also does not affect the epiphyseal quotient In a normal material the epiphyseal quotient is usually 100, but may in a few cases be as low as 85

The applicability of the epiphyseal quotient as a measure of *capital shape* is due to a rule set up by Mose Even though the epiphysis gets deformed (flattens) beyond the range in a normal material so that the epiphyseal quotient drops below 85 the above *mentioned compensatory growth* processes in the metaphysis (possibly as far down as the neck) will *maintain the normal shape of the head* so that it is not deformed beyond the normal range By careful but not quantitative observations the correctness of which I can confirm, Mose ascertained that such maintenance of *normal capital shape* occurred if only the epiphyseal quotient *exceeded 60* Thus, the epiphyseal quotient could be used as a measure of capital shape When the epiphyseal quotient exceeded 60, the shape of the head was within the normal range If *an epiphyseal quotient of 60* is not used in the radiological assessment *as the bottom* limit of normally shaped heads in *LCPD* series, but an epiphyseal quotient of *85* – which is the bottom limit of epiphyseal quotients in normal children – it is not possible to *single out all* cases with nor- [illegible] the LCPD series, [illegible] tic importance, but is a good measure of whether the treatment is able to prevent epiphyseal flattening.

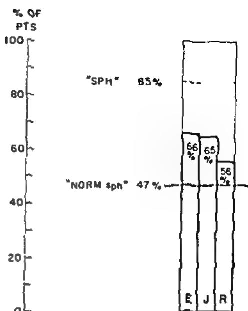
In other words, the epiphyseal quotient may be used to *single out cases* with *normally shaped heads* in a LCPD series

Below, "normal range of the epiphyseal quotient" refers simply to the range in *normally shaped heads* – comprising in a series of LCPD all epiphyseal quotients >60, *not* the range in *normal children* in whom the epiphyseal quotients never go below 85 (*cf Appendix, Comment 1*)

Now, we *have two measures of capital* shape after LCPD The *joint surface quotient* which directly measures the shape of the femoral head, and the *epiphyseal quotient* which directly measures epiphyseal shape, but indirectly may be applied – by using Mose's rule – as a measure of capital shape

Both measurements have their advantages and disadvantages One might think that the direct measurement of capital shape, the joint surface quotient, would be *preferable*, but matters are not so simple Measurement of the joint surface quotient is rather more complicated than *measurement of the epiphyseal* quotient – and therefore also carries somewhat greater uncertainty On the other hand, Mose's rule – epiphyseal quotient exceeding 60 = normally shaped head – is not based upon objective measurement, but upon an *estimate, although* it seems reliable, it is nevertheless a *subjective* estimate However, measurement of the *epiphyseal* quotient has the advantage of being the method most often used by previous authors – but rarely applying Mose's rule, and this renders the assessment of their results *somewhat more difficult*

In fact, it is difficult to decide which measuring method is more reliable As a rule their results agree, as may be expected Only, there seems to be a tendency for the difference between the results in two series to be greater measured by the epiphyseal quotient than by the joint surface quotient (The cause is not quite evident, but the phenomenon is possibly related to the application of an epiphyseal quotient >60 as a normal value, not compensating entirely for the epiphyseal shape varying more than capital shape)



However, the difference between the results of the two methods is slight – but there *are* differences, due to various inaccuracies attaching to the two methods

Considering the great importance of measuring the shape of the affected head, with a view to the risk of osteoarthritis, I preferred, whenever possible, to use *both* measurements, hoping that they could act as mutual control and thereby perhaps disclose measuring errors and accidental divergences At least, good agreement between the two measuring methods in dividing the group with spherical heads will increase confidence in the correctness of the results

The third measurement, that of the *radius quotient*, is the simplest one The radius of the affected head divided by that of the unaffected head In a normal material the radius quotient is usually 100, but may sometimes rise to 115

The main advantage of the radius quotient is that it is influenced by the size of the femoral head – which does not apply to the other two quotients In return, it is not *directly* influenced by the shape of the head The head *may* easily change in shape, i e alter from a large part of a sphere – as in normal children – to a smaller one, without its radius, and thereby its radius quotient, undergoing the slightest alteration

It is a different matter altogether that a major change in the shape of the head is usually accompanied by a greater reactive

E = % of cases healed with epiphyseal quotient > 60
J = % " " " " joint surface " > 85
R = % " " " " radius " <115

Diagram 1 Example of dividing the 'SPH group into two sub groups by means of one figure % 'NORM sph instead of into 3 x 2 groups by means of 3 figures one % for each of the 3 quotients

The patients of the material are imagined to be listed by increasing joint deformity from below and upwards

SPH = Cases healed with spherical heads

'NORM sph' = Cases healed with 'spherical' heads in which all 3 quotients are within the normal range (Ep quot >60 Jt surf quot >85, Ra quot <115)

(Abbreviations and symbols cf survey p 12)

skeletal growth in and around the joint – a greater "increase in growth" – than a minor change in shape

Therefore, a major change in shape is generally associated with a longer radius *Indirectly* then, the radius quotient is influenced by a change in shape

In practice, assessment by radius quotient is a little stricter than assessment by the other measuring methods – presumably because the radius quotient is affected by any increase in growth, also an increase *in* growth without any change in shape

However, measurement of the radius quotient has a drawback which has to be taken into account It has been a presupposition of the considerations above that the

final shape and size of the head could be determined at the time of primary healing, a year or two after completion of treatment. Indeed, this is right in all essentials – but not *quite* During the period between *primary healing* and *completion of growth, there occurs some reduction in the difference* between the affected and unaffected head, with regard to shape as well as size, mostly the latter The unaffected head grows relatively more than the affected one during continued growth until puberty Consequently, the measurements will "improve", especially the radius quotient This improvement is most marked up to the age of 9 years – and thereafter slight

Ideally, then, all measurements should not be carried out until after the completion of growth, at the age of 16, possibly after the age of 9, as thereafter the changes are negligible However, this is difficult to practice in the case of all patients Therefore, the demand must be confined to aiming at a fairly equal age distribution in the series to be compared, i e approximately equally long follow-up periods, somewhat longer in series with the earliest onset of the disease – and the largest possible number of patients over 9 years of age at the time of the measurements

From what has been stated above it is apparent that in an attempt at grouping the patients with "spherical" heads into the two groups "NORM sph" and "PATH *sph" by each* of the three radiological *measuring* methods, the size of the groups *will not be the same*

Measurement of the epiphyseal quotient and of the joint surface quotient affords approximately, but not quite the same result, whereas measurement of the radius quotient gives a somewhat smaller group of "NORM sph" than the other two

But the object was to perform *one well defined grouping that could be* expressed by 1 figure – *not* 3 *groupings* expressed by 3 figures, one *for each* measuring method

This is practicable only, if it is demanded that *the group "NORM sph." should comprise only* patients in whom *all three measuring methods afford results "within the normal range"* (epiphyseal quotient >60, joint surface quotient >85, and radius quotient <115), while the remainder – i e all cases in which merely one method gives a result beyond the normal range – are assigned to the group "PATH sph.".

This affords not only a division into two groups whose size may be expressed in 1 figure, but it also makes the group "NORM.sph." correspond better to the definition Cases healed with heads of normal shape and size (Fig. 2) The criterion of belonging to the group "NORM. sph" is thereby stricter than when based merely upon the result of one measuring method – and the size of the group consequently smaller (Diagram 1)

The distinction of such a group based upon the result of *three* measuring methods was suggested by Jorgen Lauritzen (thesis 1975) and will be used below in dividing the group "SPH"

(As to the possibility of grouping by the aid of merely one of the measuring methods, cf Appendix, Comment 3)

Let us now briefly recapitulate the *terminology* concerning the various groups of patients to be used below, in the text, tables, and diagrams (Diagram 2)

The large group of patients with spherical heads will be called "SPH" It will be divided into two sub-groups called "NORM sph" and "PATH sph" The third group, with abnormal, *irregular* heads, will be called "NON-sph"

This division of *the series into 3 groups* forms the basis *of the following* descriptions, but a *simple* division into two groups may also be *desirable* The series might be divided, for instance, into cases with normal heads and cases with abnormal heads *In that* case, the groups will be designated *simply* "NORM" and "PATH" – the former referring to the same group ■

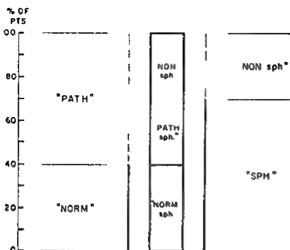


Diagram 2 Terminology in dividing an LCPD series at primary healing on the basis of the radiological shape and size of the affected femoral head

NORM = Cases healed with heads of normal shape and size (= NORM sph vide infra)

PATH = Cases healed with heads of pathological shape and/or size

SPH = Cases healed with spherical heads

NON sph = Cases healed with non spherical heads

NORM sph = Cases healed with spherical heads in which the 3 quotients Epiphyseal quotient joint surface quotient and radius quotient are within the normal range (Ep quot >60 Jt surf quot >85 Ra quot <115)

PATH sph = Cases healed with spherical heads in which one or more of the 3 quotients are outside the normal range

On the diagram the patients of the material are imagined to be listed by increasing joint deformity from bottom to top

The grouping of the material was arbitrarily selected (Abbreviations and symbols cf the survey p 12)

"NORM sph " and the latter combining the groups "PATH sph " and "NON sph " A division into two groups according to whether or not the heads are spherical may also be considered In that case the former group will be identical with "SPH ", the latter with "NON sph " These divisions into two groups are simpler, but whether they are too simple cannot be decided until later

In assessing his series, Mose used a division into 3 groups according to exactly the same principles Only, in dividing the group with spherical heads he employed just *one* measuring method *Epiphyseal quotient* The three groups of patients which resulted from this division of his series were called "good", "fair", and "poor" Although the following assessment is based upon *three* measuring methods, the terms good, fair, and poor might easily have been transferred to the three groups into which the series were divided also at the present assessment However, these terms seemed less apt, because *a priori* they included a subjective evaluation The more objective, descriptive terms "NORM sph ", "PATH sph ", and "NON-sph " were, therefore, preferred

Should it be necessary to refer to the previous "good" and "fair" groups, the new terms will be used below, merely adding a letter to designate the measuring method used, e g "NORM sph " (J) or "PATH sph " (E)

If it seems expedient to base the grouping upon two measuring methods – omitting e g the result of the radius quotient measurement – this is of course also practicable, if only the resulting groups are appended by two letters (J E)

Diagram 2 gives a survey of the terminology used in the present paper

A list of abbreviations is given on p 12

2 Results in the Series as Referred

As already mentioned, the results obtained in the series as they were referred depend not only upon the treatment, but also upon sex and upon the patients' age and the stage of the disease at institution of treatment

The results to be reported in this section are due to an interaction of all these factors As the series very probably differ not only in the treatment received, but also in the other factors the results tell us

nothing about the effect of these treatments under uniform conditions

In the next section it will be endeavoured to elucidate this — *our main problem*

In assessing all therapeutic results below most emphasis will be laid *upon the number* of patients with normally spherical femoral heads — the percentage size of the normal group *designated* "NORM sph"

This percentage is considered as a measure of the number of good results obtained by the treatment

It is only in this group that the shape and size of the head is within the normal range and *therefore the risk of osteoarthritis cannot essentially exceed that of* primary osteoarthritis in normal persons This must be called a satisfactory result and if this is set up as a reasonable and well-defined criterion of the desired *result only the cases of the group* "NORM sph" can be classified as good radiological results

In patients of the group "PATH sph" on the other hand the shape and size of the head are definitely abnormal and the risk of osteoarthritis accordingly greater than in people with previously healthy hips Thus if it is maintained that the risk of osteoarthritis in normals is the criterion of a good result such a result is not obtained by the patients of the group "PATH sph" These patients are bound to develop osteoarthritis of a *somewhat* greater frequency and severity than would a corresponding group of normal persons

However it is possible and it has been claimed that in actual fact these cases of osteoarthritis are so few and so mild that in practice it would be justified to call them good clinical results If so all cases of the large radiological group "SPH" could be called radiologically satisfactory

If this were right it would *mean that* articular deformities far beyond the normal range *would have to be* accepted as good radiological results

A priori this does not seem likely — Fig 1 — and is at least pending further analysis *quite uncertain*

As a preliminary point of view therefore only cases of the group "NORM sph" can be considered satisfactory radiological results

An essential part of the later clinical sections then will be devoted to proving — or disproving — the correctness of this viewpoint i e to investigating whether and if so to what extent osteoarthritis develops in the pathologically deformed part of the group "SPH" — i e in "PATH sph"

Therefore in the following radiological sections the main emphasis will be on establishing (and depicting) the size of the group "NORM sph" *Owing to the uncertainty* concerning the development of osteoarthritis in "PATH sph" however the size of the entire "SPH" group — and thus also of "PATH sph" — will be recorded

The radiological assessment concerned three series treated by three different methods

1 *113 patients* viz all patients *treated for* unilateral LCPD in the Seaside Hospital Refsnæs during the period 1958–1963 The majority (about 3/4) were treated *by bed rest plus traction* for one year *followed by bed rest* without traction *for 6 months* + ambulatory non weight bearing for another 6 months (for further details of the treatment cf Meyer 1966 p 54) One quarter of the *patients* who were not or only briefly treated by *traction* had bed rest without traction This is the "traction series" *described* by Meyer (1966) *supplemented* by 42 patients Below it will be designated the "*traction series*"

2 *114 patients* viz *all* patients started on treatment for unilateral LCPD in the Orthopaedic Hospital Århus *during the* period 1957–1964 All had ambulatory treatment in a wheelchair For details of

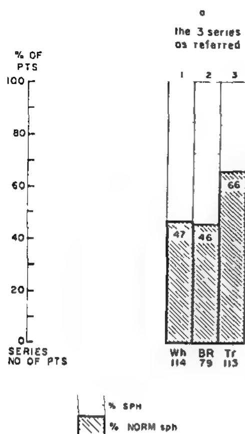

Diagram 3 Radiological results of treating

2 the BR series as referred by BR (73 %)
3 the Tr series as referred by Tr (84 %)

(1 2 and 3 signify Wh BR and Tr treatment)

A total tabulation of the radiological results is given in the Appendix Table 27

Statistical calculation

There is a significant difference in the frequency of patients with "normal spherical" heads ("NORM sph") between

the Tr series and Wh series as referred ($p < 0.01$) and
the Tr series and BR series as referred ($p < 0.01$)
(cf also Appendix Table 28)

(Abbreviations and symbols on p 12)

this treatment, cf Lauritzen (1975) This series will be referred to below as the "*wheelchair series*"

3 *79 patients*, viz *all* those treated for unilateral LCPD in the Seaside Hospital, Refsnæs, during the period 1953–1957 Treatment Bed rest without traction in hospital for 18 months, followed by ambulatory non-weight-bearing for 6 months. This series has previously been published by Mose (1964) and Meyer (1966). Below it will be designated the *"bed rest series"*.

The following abbreviations will be used, to save space, on diagrams and tables

Wh = wheelchair
BR = bed rest without traction
Tr = bed rest with traction

These abbreviations will be used either alone or in combinations, e g Wh series, Tr treatment, etc

According to the lines described above, each of these series will be divided into three groups of patients "NORM sph", "PATH.sph", and NON-sph".

The results are apparent from Diagram 3 and Table 1 (details in the patient lists) and from the Appendix, Tables 22, 23, 24

Table 1 Radiological results of wheelchair (Wh), bed rest (BR), and traction (Tr) treatment in the three series (as referred) (No of pts, cf Appendix, Table 26)

Radiological groups	Wh series 114 pts	BR series 79 pts	Tr series 113 pts
	%	%	%
"NON-sph"	15	27	16
"PATH sph"	38	27	18
"NORM sph"	47	46	66

The follow-up periods and patient age at the time of measurement are shown in Table 2

There might have been better agreement – but it seems acceptable In practice, it is difficult to attain complete agreement It proved necessary to carry out new measurements on the traction series three years after the first ones, as at that time the follow-up period had been far too short and patient age too young The results of this new measurement were in striking conformity with those of the former except for the expected, moderate improvements due to the longer follow-up period

Table 2. Follow-up period and patient age at the time of measurement in the Wh BR and Tr series.

	Follow-up period after institution of treatment (mean)	% of pts. ≥9 years at time of measurement
Wh series (114 pts.)	5½ years	81 %
BR series (79 pts.)	4½ years	83 %
Tr series (113 pts.)	6 years	92 %

These improvements were of modest, but not inconsiderable extent Thus, the percentage of "NORM sph" had increased from 61 % to 66 %

From Diagram 3 it is evident that the percentage size of the "NORM sph" group, i e *the percentage of "good results"* in the wheelchair and bed rest series was practically the same, viz 47 % and 46 %, but appreciably higher in the traction series, 66 %

Considering the fairly uniform follow-up periods and ages at measurements, these three values ought to be comparable as an expression of the efficacy of the three methods of treatment, i e only in the series as referred without paying regard to possible differences in sex and in age as well as stage of disease at institution of treatment

From Diagram 3 (and Table 1) it is apparent incidentally, that the *group SPH* ("NORM sph" + "PATH sph") made up 85 % 73 % and 84 % of the wheelchair, bed rest, and traction series respectively

Thus the percentage of "SPH" was the same in the wheelchair and traction series despite the fact that the percentage of "NORM sph" was considerably lower in the wheelchair than in the traction series

This was unexpected in so far as in 1966 Meyer measuring the epiphyseal quotient in four series found the percentage of *"SPH" to vary in all series* by the percentage of "NORM sph" (E) (Meyer 1966, Diagram 20) – only with smaller differences This applied also to the joint surface quotient and radius quotient – and there is no reason why it should not apply also to "NORM sph." calculated on the basis of all three measuring methods Indeed, Diagram 3 shows that it applies to the bed rest series and the traction series. Only the values for the Wh series were not *according to the rule.*

It is difficult to elucidate the cause. The values were found in the series as referred – and as they were not of the same prognostic severity, the values are not directly comparable The apparent disagreement is probably due chiefly to the different nature of the series However, the mechanism of action of the treatments may be operative All considered, it does not seem reasonable to ponder too much, at this site, upon the cause of the peculiarity in the wheelchair results This is better deferred until the next sections which deal with the therapeutic results in comparable groups of patients

The main results of the analysis in the present section, then, may be briefly summed up as follows

By the three methods of treatment in the series as referred, about half the patients of the *wheelchair series* and of the *bed rest series* obtained what is called, at least preliminarily, a good radiological result, as they belong to the group "NORM sph" In the *traction series* this result was found in about two-thirds of the patients

Contrary to expectation, the more comprehensive *group "SPH"* proved to be of the same size in the wheelchair and traction series despite the pronounced difference in "NORM sph" However, the groups are of the same size *only quantitatively*, while qualitatively the group "SPH" in the wheelchair series is appreciably inferior to that in the traction series It includes a far smaller number of cases that can be classified as "NORM sph"

In the bed rest series, the size of the "SPH" *group* is, as might be expected,

smaller than in the traction series – corresponding to the smaller group "NORM sph." in the bed rest series

3. Results in Series Differing Only – As Far As Possible – in Therapeutic Methods

The results described in the preceding section express only the efficacy of the treatment in the series as referred – with the differences that may exist with regard to sex, age, and stage of the disease at institution of treatment

Thus, the results are determined not only by the various methods of treatment, but also by the three factors mentioned above

However, the main problem of the present study was the relative efficacy of the treatments under *uniform* conditions, i e in series varying only with regard to the treatment, not the other factors

Further elucidation of this problem will be attempted below

First, the variation of the three factors in the series must be mapped – if they vary at all

Patients' age at institution of treatment was as shown in Table 3

Table 3 Age distribution in the Wh BR and Tr series Percentage of patients in the series (for No of pts cf Appendix Table 26)

Series treated by	Age groups I ≤4 years	II 5–8 years	III ≥9 years
	%	%	%
Wheelchair (114 pts)	32 5	60 5	7
Bed rest without traction (79 pts)	21	61	18
Traction in bed (113 pts)	27	55	[illegible]

It is apparent that in the wheelchair series the percentage of patients in the youngest group is higher and that of patients in the oldest group lower than in the other two series The bed rest series is from the prognostic point of view the "heaviest" one, having a lower percentage of patients in the youngest group than the traction series, while in the oldest groups these series showed the same percentage ($2\frac{1}{2}$ times that of the wheelchair series (18 %/7 %)

Somewhat more uncertainty attaches to classification of the series by *stage* of disease at institution of treatment

A classification into three groups was made, by condition of the epiphysis at institution of treatment

A Epiphysis condensed – but without flattening or fragmentation

B Epiphysis condensed and flattened, but without fragmentation

C Epiphysis distinctly fragmented

Whether a condensed epiphysis – the first two groups – was flattened even before institution of treatment was determined by measurement

This measurement was carried out exactly like that of the epiphyseal quotient after completion of the treatment By measuring epiphyseal height and width These two measurements afford a numerical expression of epiphyseal flattening

To avoid confusion with the epiphyseal quotient, measured *after* completion of the treatment, this new quotient, measured at institution of treatment was called, at the suggestion of J Lauritzen, the *INITIAL QUOTIENT* Measurements of the epiphyseal quotient in normal persons have shown that without any signs of disease in the epiphysis this quotient may range from 100 down to 85 Therefore the epiphysis was deemed not flattened at institution of treatment when the similarly measured initial quotient exceeded 85, whereas an initial quotient below 85 indicated flattening of the affected epiphysis

As group C, I classified cases in which the epiphysis was so fragmented as not to permit measurement of the initial quotient

In practice, however, it was soon apparent that group C cases were so few and so difficult to distinguish definitely from group B cases that it seemed reasonable to combine these groups into a larger group B Below, then, we shall operate with two groups An *"early" group A* and a *'late" group B* These groups are distinguished by measurement of the flattening of the condensed epiphysis – a measurement which is adequately well-defined and therefore affords reasonably definite distinction Group A is of a far more uniform composition than group B, which contains cases in which the epiphysis was merely condensed but flattened as well as cases with severely fragmented epiphyses

Table 4 Distribution by "early' and 'late treatment in the three series. Percentage of patients in the series. (For No of pts cf Appendix Table 26)

A Cases in the stage of condensation without flattening (initial quot >85) at institution of treatment

B The remainder – i e cases in the stage of condensation with flattening (initial quot ≤85) and cases in the stage of fragmentation at institution of treatment

Cases of Dysplasia epiphysialis capitis femoris without flattening (J.M 1964) are assigned to group A

Series treated by	Stage at institution of treatment Early treatment *A*	 Late treatment *B*
	%	%
Wheelchair (114 pts)	65	35
Bed rest without traction (79 pts.)	49	51
Traction in bed (113 pts)	55	45

Table 4 gives the distribution into groups A and B of the three series

It will be seen that in the wheelchair series a larger number of patients had early treatment than in the other two series The largest number of cases having late treatment was found in the bed rest series

The sex ratio may be seen from Table 5

The largest number of girls were in the bed rest series, the smallest in the traction series while the wheelchair series was in

Table 5 Sex ratio in the Wh BR and Tr series. Percentage of patients in the series (No of pts. cf Appendix Table 26)

Series treated by	Sex ♂	 ♀
	%	%
Wheelchair (114 pts.)	82	18
Bed rest without traction (79 pts.)	76	24
Traction in bed (113 pts.)	86	14

between The differences are not inconsiderable, but are no doubt due to chance However, they seem too marked to be left out of account

If, after having mapped the variation of the three factors in the series, we can pick out three groups of patients, one from each series, in which all three factors are identical and only the methods of treatment have varied, the results in these groups are determined solely by the efficacy of the treatment Thereby, it would be possible to gain a clear impression of the relative efficacy of the three methods of treatment in these groups – ridded of the influence of other factors

Let us first try to obtain three groups of patients in which two factors – *age* and *stage* of disease at institution of treatment – were as uniform as possible

This may be achieved by combining Tables 3 and 4 in the way that each of the series is divided into six groups

$$A_I - A_{II} - A_{III} - B_I - B_{II} - B_{III}$$

The first group, A_I – patients under 5 years of age who had early treatment – is then the "lightest" one, i e the one in which the best results may be expected The last group B_{III} comprises the oldest children who had late treatment, and therefore the results must be expected to be poorest The prognostic severity of the intermediate groups will – broadly speaking – increase from left to right

Since, however, age has most influence upon the results, the results in group A_{III}

Table 6 Composition of the series with regard to patients' age and stage of disease at institution of treatment (No of pts, cf Appendix, Table 26)
Meaning of I, II III, and A, B, cf Tables 3 and 4
% = % of all pts in the series

Series treated by	Age/stage groups					
	A I	A II	A III	B I	B II	B III
	%	%	%	%	%	%
Wheelchair (114 pts.)	21	40	4	11	20	4
Bed rest without traction (79 pts.)	6	30	12	16	30	6
Traction [redacted] bed (113 pts)	12	29	14	15	26	4

are often inferior to those in groups B_I and B_{II} If the sequence is to correspond to the increasing severity, group A_{III} ought to be moved between groups B_{II} and B_{III}. This will be done when such a sequence is desired

The result of the classification [redacted] presented in Table 6

It shows that the "lighter" nature of the *wheelchair series* is even more apparent in this combination of Tables 3 and 4

A look at the number of patients in each group shows that it is regrettably small Group A_{II} is the largest one, and the only single group which is perhaps sufficiently large to permit an attempt at determining the relative efficacy of the treatments in the three series In another way too A_{II} must be presumed to be suited In the very mild cases the nature of treatment [redacted] presumably of less importance to the results Practically all will be good, no matter what the treatment About the same applies to the most severe cases All results are more or less poor, regardless of the treatment Group A_{II} belongs to the intermediate groups in which the efficacy of the treatments will probably manifest itself more clearly.

However, the *sex ratio* in the groups is not the same

The percentage of girls in the A_{II} groups of the Wh, BR, and Tr series is 13 %, 21 %, and 18 % respectively The difference between these percentages is not inconsiderable (but no doubt due entirely to chance) Since, however, the difference in therapeutic results in girls and boys is slight, the difference in the sex ratio within the three series is not likely, in spite of all, to have any major influence upon the results But it is necessary first to make sure that this assumption is correct

The only way in which we can avoid an effect of a difference in sex ratio is by performing all analyses *only on the boys* who make up about 4/5 of all the series Therefore, such analyses will be carried out to check whether the result of analysing the groups with both sexes have afforded sufficiently reliable information about the

Table 7 Results of treatment in age/stage groups in the Tr Wh and BR series as referred (No of pts cf Table 24 Appendix Table 26)
% = % NORM sph in the groups

Series treated by	Age/stage groups					
	A I	A II	A III	B I	B II	B III
	%	%	%	%	%	%
Wheelchair (114 pts)	79	48	0	46	30	0
Bed rest without traction (79 pts.)	80	54	30	58	29	(50)
Traction in bed (113 pts)	100	85	27	76	52	20

relative efficacy of the three therapeutic methods – or whether a correction for the slight sex difference is needed

In other words, the main study will be on the undivided groups and series, comprising both sexes Analysis of the boys alone was only done as a supplement

The results obtained in the 6 groups into which the three "mixed" series were divided may be seen from Table 7 – or perhaps more clearly from Diagram 4 (only for the Wh og Tr series)

From the table as well as the diagram it is apparent that largely the results get poorer the older the patients are and the later they arrive for treatment This applies also when analysing separately the relationship of the course to age and stage There are few exceptions to this rule It is evident also that the difference between the results of the three treatments – especially between Tr and the other two – is most marked in the intermediate groups (A_{II} and B_{I}), less in the "milder" and very "severe" cases This is even more distinct in Diagram 5 in which the 6 groups are combined, in various ways, into 9, so that the transition from the mildest to the most severe group is more even and the number of patients in each group larger However, these combined groups are appreciably less uniform and comparable than the 6 main groups

Out of these six groups A_{II} is best suited to our purpose To determine the results of

RADIOLOGICAL RESULTS
IN THE Wh AND Tr SERIES

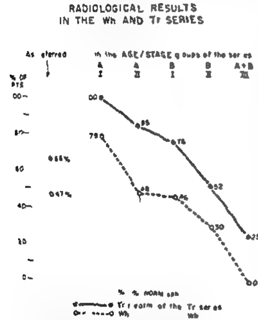

Diagram 4 Radiological results in the Wh and Tr series as referred and in the age/stage groups of these series

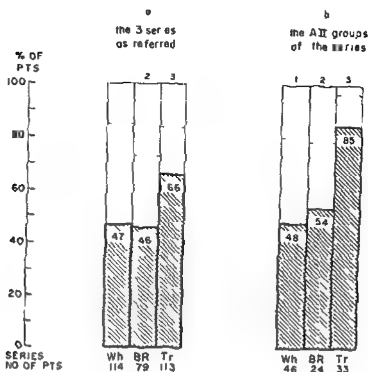
As the results in the oldest age group (III) are poor regardless of stage the groups A III and B III (which are very small) were combined into one (A III + B III) This affords a larger number of patients as well as a sequence of the groups from left to right according to decreasing results.

(Abbreviations and symbols as listed p 12
% given in number of pts in the Appendix Table 26)



RADIOLOGICAL RESULTS
IN THE Wh AND Tr SERIES

Diagram 5 Radiological results in the Wh and Tr series as referred as well as in age/stage groups of these series of increasing severity from left to right

The age/stage groups in this diagram are combined groups having a larger number of patients and a more even transition from the mildest to the most severe group than the 6 simple groups on Diagram 4 However the combined groups in both series are less comparable than the 6 simple ones.

(Abbreviations and symbols as listed p 12

There was s gnificant difference in the frequency of pts with normally spherical heads (NORM sph) between
the A II groups of the Tr series and Wh ser es ($p < 0.01$) and
the A II groups of the Tr series and BR series ($p < 0.05$)

the three methods of treatment in uniform groups of patients

The result of such an analysis is present ed in Diagrams 6–7

From Diagram 6 it may be seen that the differences between the results of the three treatments are more pronounced in the A_{II} groups (uniform with regard to age and stage) than in the total series of a more heterogeneous composition

By *wheelchair* and *traction* treatment 47 % and 66 % good results i e NORM sph were obtained in the total series in the more uniform A_{II} groups 48 % and 85 % respectively By *wheelchair* and *bed rest* 47 % and 46 % NORM sph were obtained in the total series in the A_{II} groups 48 % and 54 % respectively

These appreciably increased differences in the A_{II} groups are explicable as follows

(perhaps best *illustrated in* Diagram 7)

The results in the *traction* and *bed rest* series improve on transition from total series to groups A_{II}, because removal of the heavy part of these severe series (groups A_{III} and $B_{I-II-III}$) has more effect than removal of the small, mild A_I groups. In the *wheelchair series,* on the other hand, the removal of the heavy *end of the series* counterbalances the *removal of* the numerically larger *mild* group A_I in the way that the result in group A_{II} of the wheelchair series is largely identical with that in the total series.

Thus, the more marked differences in therapeutic results between the more uniform A_{II} groups ought to afford a more reliable picture of the *relative efficacy of the therapeutic methods* than do the less marked differences in the total series as referred, which are not uniform with regard to severity (Statistical calculation cf legend to Diagrams 3 and 6)

However, the A_{II} grups have two essential *defects. In the first place they are too small* comprising *only 46, 24, and 33* patients respectively. Therefore, chance may influence the results. However, it must be mentioned that the shape of the curves in Diagram 4, without any inexplicable kinks does not indicate that they are *characterized by* chance. In the second place the *sex ratio is not the same,* as already mentioned there *being rather more* girls in the A_{II} group of the traction and bed rest series than in the wheelchair series.

But both defects can be remedied

The uncertainty attaching to the small *number of* patients in the A_{II} groups may be reduced, if we do not restrict the analyses to utilizing *only the results in the* A_{II} groups, but include the results *in all* groups. Basing the analysis on a larger number of patients and patient groups ought to increase the statistical reliability.

This may be practised as follows

Among the *114* patients of the wheelchair series 47 % good *results* (% "NORM sph ") were obtained — by wheelchair treatment. The material was then divided *into six groups,* so that the patients within each *group* were *uniform* with respect to age/stage at institution of *treatment.* The 113 patients of the traction series were divided into corresponding groups, each comprising cases of as far as possible exactly the same severity at admission as the corresponding groups of the wheelchair *series. Thus, one* treatment ought to afford the same *result in* two corresponding groups. In other words *If e group* A_{II} of the wheelchair series *had been treated by traction,* it would have shown the *same* result as the A_{II} group of the traction series

Re results in the A II groups of the series
There is a significant difference in the frequency of pts with normally spherical' heads (NORM sph) between
the A II groups of the Tr series and Wh series ($p < 0\ 01$) and
the A II groups of the Tr series and BR series ($p < 0\ 05$)

the three methods of treatment in uniform groups of patients

The result of such an analysis is presented in Diagrams 6 7

From Diagram 6 it may be seen that the differences between the results of the three treatments are more pronounced in the A_{II} groups (uniform with regard to age and stage) than in the total series of a more heterogeneous composition

By *wheelchair* and *traction* treatment 47 % and 66 % "good" results i e "NORM sph " were obtained in the total series in the more uniform A_{II} groups 48 % and 85 % respectively By *wheelchair* and *bed rest* 47 % and 46 % "NORM sph " were obtained in the total series – in the A_{II} groups 48 % and 54 % respectively

These appreciably increased differences in the A_{II} groups are explicable as follows

perhaps best illustrated in Diagram 7)

The results in the *traction* and *bed rest* series improve on transition from total series to groups A_{II}, because removal of the heavy part of these severe series (groups A_{III} and $B_{I-II-III}$) has more effect than removal of the small, mild A_I groups In the *wheelchair series*, on the other hand, the removal of the heavy end of the series counterbalances the removal of the numerically larger mild group A_I in the way that the result in group A_{II} of the wheelchair series is largely identical with that in the total series

Thus, the more marked differences in therapeutic results between the more uniform A_{II} groups ought to afford a more reliable picture of the relative efficacy of the therapeutic methods than do the less marked differences in the total series as referred, which are not uniform with regard to severity (Statistical calculation cf legend to Diagrams 3 and 6)

However, the A_{II} grups have two essential defects In the first place they are too *small* comprising only 46, 24, and 33 patients respectively Therefore, chance may influence the results However, it must be mentioned that the shape of the curves in Diagram 4, without any inexplicable kinks, does not indicate that they are characterized by chance In the second place, the *sex ratio* is not the same, as already mentioned, there being rather more girls in the A_{II} group of the traction and bed rest series than in the wheelchair series

But both defects can be remedied

The uncertainty attaching to the small number of patients in the A_{II} groups may be reduced, if we do not restrict the analyses to utilizing only the results in the A_{II} groups, but include the results in *all* groups Basing the analysis on a larger number of patients and patient groups ought to increase the statistical reliability

This may be practised as follows

Among the 114 patients of the wheel chair series 47 % good results (% "NORM

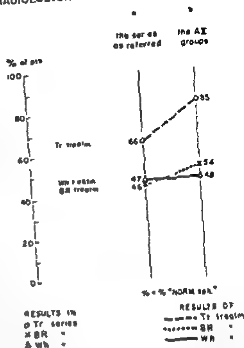

Diagram 7 Radiological results of treating the Wh, BR, and Tr series as referred (a) and their A II groups (b)

Re results in the series as referred cf Diagram 3
Re results in the A II groups of the series
There is a significant difference in the frequency of pts with normally spherical heads (NORM sph) between
the A II groups of the Tr series and Wh series ($p < 0.01$) and
the A II groups of the Tr series and BR series ($p < 0.05$)

the three methods of treatment in uniform groups of patients

The result of such an analysis is presented in Diagrams 6 7

From Diagram 6 it may be seen that the differences between the results of the three treatments are more pronounced in the A_{II} groups (uniform with regard to age and stage) than in the total series of a more heterogeneous composition

By *wheelchair* and *traction* treatment 47 % and 66 % "good" results i e "NORM sph " were obtained in the total series in the more uniform A_{II} groups 48 % and 85 % respectively By *wheelchair* and *bed rest* 47 % and 46 % "NORM sph " were obtained in the total series – in the A_{II} groups 48 % and 54 % respectively

These appreciably increased differences in the A_{II} groups are explicable as follows

perhaps best illustrated in Diagram 7)

The results in the *traction* and *bed rest* series improve on transition from total series to groups A_{II}, because removal of the heavy part of these severe series (groups A_{III} and $B_{I-II-III}$) has more effect than removal of the small, mild A_I groups. In the *wheelchair series*, on the other hand, the removal of the heavy end of the series counterbalances the removal of the numerically larger mild group A_I in the way that *the result in group* A_{II} of the wheelchair *series* is largely identical with that in the total series

Thus, the more marked differences in therapeutic results between the more uniform A_{II} groups ought to afford a more reliable picture of the relative efficacy of the therapeutic methods than do the less marked differences in the total series as *referred, which are not uniform* with regard to severity (Statistical calculation cf legend to Diagrams 3 and 6)

However, the A_{II} grups have two essential defects In the first place they are too *small* comprising only 46, 24, and 33 *patients respectively* Therefore, chance may influence the results *However, it must* be mentioned that the shape of the curves in Diagram 4 without any inexplicable kinks does not indicate that they are characterized by chance In the second place, the *sex ratio* is not the same, as *already mentioned*, there being rather more girls in the A_{II} group of the traction and bed rest series than in the *wheelchair series*

But both defects can be remedied

The uncertainty attaching to the small number of patients in the A_{II} groups may be reduced, if we do not restrict the *analyses* to utilizing only the results in the A_{II} *groups*, but *include* the results in *all* groups Basing the *analysis on a* larger number of patients and patient *groups* ought to increase the statistical reliability

This may be practised as follows

Among the 114 patients of the wheelchair series 47 % good results (% "NORM sph ") were obtained – by wheelchair treatment The material was then divided into six groups, so that the patients within each group were uniform with respect to age/stage at institution of treatment The 113 *patients of the traction series were* divided into *corresponding groups*, each comprising cases of as far as possible exactly the same severity at admission as the corresponding groups of the wheelchair series Thus, *one* treatment ought to afford the same result in two corresponding *groups* In other words *If* e g group A_{II} of the wheelchair series *had been treated by traction*, it would have shown the same result as the A_{II} group of the *traction* series

RADIOLOGICAL RESULTS OF TREATING

3. the Wh series as referred by Tr (calculated) (91 %)

% SPH
% "NORM sph"

(A total tabulation of the radiological results in the Appendix Table 27 Abbreviations and symbols p 12)

In c the Wh series as referred could be replaced with 3 identical series composed like the Wh series (with regard to patients age and stage of disease at institution of treatment)

Thus the results in a have been obtained by Wh BR and Tr treatment of 3 series which were in respect to pts age and stage of disease at institution of treatment very different heterogeneous The results in b have been obtained by treating groups of patients (A II groups) almost uniform in these respects those in c by treating 3 entirely identical series composed like the Wh series

If now we transfer the percentage results from *all* six groups of the *traction* series to the corresponding patient groups in the *wheelchair* series it is possible to find the number of patients in each of the six groups of *the wheelchair series* who would have obtained a good ' result i e a "normal spherical' head by traction By addition this number may be found for the total wheelchair series – and thereby the percentage of NORM sph ' that would have been obtained *if the total wheelchair series had been treated by traction* In the same way it is possible of course to calculate the result that would have been obtained by bed rest treatment of the wheelchair series

Hereby we have ascertained how one series of a given composition and of considerable size like the wheelchair series

will respond to *three different treatments* In other words the three results are comparable expressing the different efficacy of the three therapeutic methods in *one* series – or if you will in *three* identical series – *of a composition like the wheelchair series*

Of course it may be calculated, in the same way what the three treatments could have effected *in the traction series* and *in the bed rest series*

Diagrams 8–9–10 set out the results of these calculations (showing for comparison the results in the series as referred and their A_{II} groups)

It is evident that the results of the three methods of treatment in the wheelchair series do not differ essentially from those in the A_{II} groups (Diagram 8) Only, the difference between the results of traction and *wheelchair treatment* are *somewhat* less marked than in the A_{II} groups, simply because the differences in the "light" and "heavy" groups, now included, are less than in the A_{II} groups (Diagram 4) and therefore reduce the difference in the total wheelchair series On the other hand, the difference between the results of *bed rest* and *wheelchair* treatment are not inferior

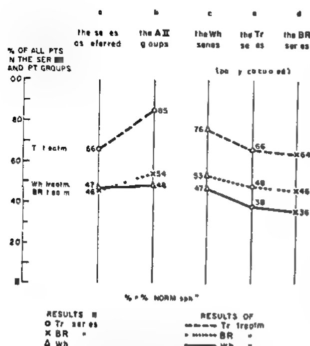

Diagram 10 Survey of the radiological results set out in Diagrams 8 and 9 (but excluding % SPH")

On this survey diagram each set of 3 columns from Diagrams 8 and 9 is replaced with a more simple symbol a vertical line

The 3 small symbols on the vertical lines signify the results in the 3 series as referred and their A II groups

The oblique lines between the vertical ones connect the results of the same form of treatment

(A total tabulation of the radiological results is given in the Appendix Table 27 Abbreviations and symbols on p 12)

to those in the A_{II} groups Calculation of the differences in the traction and bed rest series even shows them to be somewhat greater (Diagrams 9–10), because the differences between the results in the other groups with bed rest and wheelchair treatment were *not* less than those in the A_{II} group On the contrary, the difference is most marked in group B_I (Table 7)

Thus, the results of the three methods of treatment in the *wheelchair* series did not differ essentially from the results in the A_{II} groups. When calculated for the *traction* and *bed rest* series on the other hand, the results of the three methods of treatment are on the whole somewhat inferior to those in the wheelchair series, simply because these are heavier series – the bed rest series most severe (Diagrams 9–10) However, as in the wheelchair series, the relative values of the results correspond quite well to those found in groups A_{II}

In other words The deviations from the results in the A_{II} groups found by including the results in all groups in the analysis are fully explained by the difference between the A_{II} groups and the total series

The result of the calculations, then, has given no reason to believe that the results in the A_{II} groups are characterized by chance because of too small numbers of patients According to the finding, the results in *the* A_{II} *groups afford* a reliable impression of the effect of the three treatments as to the radiological result in a group of medium severity

It now remains to be seen whether the other source of uncertainty in analysing the results in the A_{II} groups – the heterogeneous sex ratio in the groups – has appreciably affected the results

This uncertainty naturally applies to all results in groups and series comprising both sexes (mixed) Therefore, the study was carried out in the way that all analyses and calculations in such mixed series were performed *on boys only* Thereafter, the results were compared with those in mixed groups

As the therapeutic results are somewhat more favourable in boys than in girls, a study on boys alone would be expected to show rather better therapeutic results – and perhaps altered differences in results between the three treatments

Diagrams 11, 12, and 13 as well as Tables 8 and 9 show that in all essentials they did

But the percentage of "NORM sph " for boys alone in the wheelchair series is nevertheless not essentially better than in the corresponding mixed groups of patients This is because in the wheelchair series the results were equally good for girls and for boys In the traction and bed rest

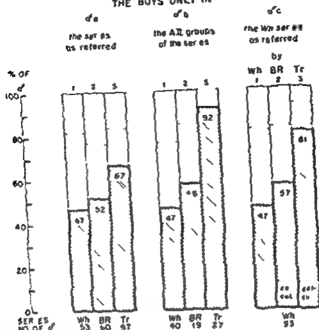

Diagram 11 Radiological results of treating the BOYS alone in

% "SPH"
% NORM sph"

(1 2 and 3 signify Wh BR and Tr treatment respectively)

For comparison Diagram 8 shows the results of treating GIRLS + BOYS in the corresponding mixed series and groups of patients

(A total tabulation of the radiological results is given in the Appendix Table 27 Abbreviations and symbols on p 12)

Statistical calculations concerning the results of treating BOYS only

There was a significant difference in the frequency of patients with normally spherical" heads ("NORM sph) between

ads (SPH) between

series on the other hand the results were poorer for girls than for boys so that the results were improved by omitting the girls

Thus the boys' A_{II} groups are uniform with regard to age and stage at institution of treatment as well as sex – the factors, apart from the treatment, which determine the results

More uniform groups of patients cannot be set up

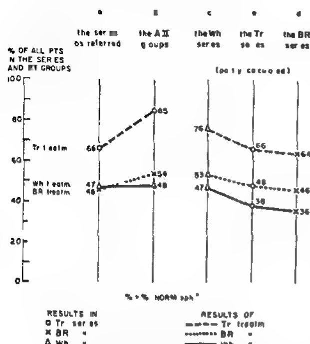

Diagram 10 Survey of the radiological results set out in Diagrams 8 and 9 (but excluding % ' SPH ')

On this survey diagram each set of 3 columns from Diagrams 8 and 9 is replaced with a more simple symbol a vertical line

The 3 small symbols on the vertical lines signify the results in the 3 series as referred and their A II groups

The oblique lines between the vertical ones connect the results of the same form of treatment

(A total tabulation of the radiological results is given in the Appendix Table 27 Abbreviations and symbols on p 12)

to those in the A_{II} groups Calculation of the differences in the traction and bed rest series even shows them to be somewhat greater (Diagrams 9–10), because the differences between the results in the other groups with bed rest and wheelchair treatment were *not* less than those in the A_{II} group On the contrary, the difference is most marked in group B_I (Table 7)

Thus, the results of the three methods of treatment in the *wheelchair* series did not differ essentially from the results in the A_{II} groups When calculated for the *traction* and *bed rest* series, on the other hand, the results of the three methods of treatment are on the whole somewhat inferior to those in the wheelchair series, simply because these are heavier series – the bed rest series most severe (Diagrams 9–10) However, as in the wheelchair series, the relative values of the results correspond quite well to those found in groups A_{II}.

In other words The deviations from the results in the A_{II} groups found by including the results in all groups in the analysis are fully explained by the difference between the A_{II} groups and the total series

The result of the calculations, then, has given no reason to believe that the results in the A_{II} groups are characterized by chance because of too small numbers of patients According to the finding, the results in *the* A_{II} *groups afford* a reliable impression of the effect of the three treatments as to the radiological result in a group of medium severity

It now remains to be seen whether the other source of uncertainty in analysing the results in the A_{II} groups – the heterogeneous sex ratio in the groups – has appreciably affected the results

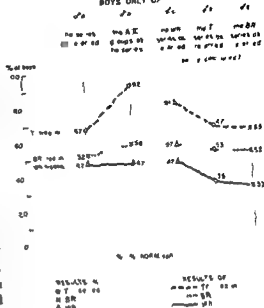
This uncertainty naturally applies to all results in groups and series comprising both sexes (mixed) Therefore, the study was carried out in the way that all analyses and calculations in such mixed series were performed *on boys only* Thereafter, the results were compared with those in mixed groups

As the therapeutic results are somewhat more favourable in boys than in girls, a study on boys alone would be expected to show rather better therapeutic results – and perhaps altered differences in results between the three treatments

Diagrams 11, 12, and 13 as well as Tables 8 and 9 show that in all essentials they did

But the percentage of "NORM sph " for boys alone in the wheelchair series is nevertheless not essentially better than in the corresponding mixed groups of patients This is because in the wheelchair series the results were equally good for girls and for boys In the traction and bed rest

fluctuations are less marked (*Diagram 11*) (cf also p 23)



The results of the three treatments of the boys in each of the three total series – wheelchair bed rest, and traction series – bore exactly the same relationship to the results in the boys' A_{II} groups as did the corresponding results in the mixed total series to the results in the mixed A_{II} groups (Diagram 13) (For statistical calculation concerning the results in boys only cf legend to Diagram 11 and survey in the Appendix Table 28)

Now it has been attempted to control the drawbacks which indubitably attach to the *mixed* A_{II} groups – the small number of patients and the varying sex ratio – and which have distorted the results found in these groups In part it has been attempted to base the analyses on a larger number of patients all *patients in the total series* and in part the studies have been carried out *solely on boys*

True the results have shown divergences from those found in the mixed A_{II} groups but in all essentials such divergences have been explicable as a consequence of the different nature of the various patient groups – more mild and severe cases in the total series the milder disease in the boys as compared with the girls

It may therefore be rightly concluded that the results in the mixed A_{II} groups afford by and large a reliable impression of the relative efficacy of the three thera peutic methods in these groups of patients

Wheelchair bed rest and traction give 48 % 54 % and 85 % "NORM sph" respectively

On th s survey diagram each set of columns from the two diagrams has been replaced with a more simple symbol a vertical l ne

The 3 small symbols on the vertical lines signify the results in the boys of the 3 series as referred and in their ♂A II groups.

The oblique l nes between the vertical ones connect the results of the same form of treatment

For comparison Diagram 10 gave the corresponding results of treating GIRLS + BOYS i.e the results in the mixed series and groups.

(A total tabulation of the radiological results is given in the Appendix Table 27 Abbreviations and symbols p 12)

% SPH
% NORM sph"

The results of treating GIRLS + BOYS in the mixed series were given in Diagram 9

(A total tabulation of the radiological results Appendix Table 27 Abbreviations and symbols cf survey p 12)

Therefore, the results in these groups ought to afford the *most reliable impression of the relative efficacy of the three methods of treatment* in these special groups of boys – more reliable than the results in the less uniform mixed A_{II} groups

Wheelchair bed rest, and traction treatment in the *A_{II} groups of boys* gave *47 % 58 %, and 92 %* "NORM sph " respectively The differences are somewhat more pronounced than in the *mixed A_{II} groups (48 %, 54 % and 85 %)* The natural explanation is that the girls make up the "heavy" end of the mixed groups and therefore dampen the differences in the therapeutic results It should be mentioned that in these optimally comparable groups the changes in the "SPH " percentage follow those in the "NORM sph " from the traction series through the bed rest series, to the wheelchair series only, the

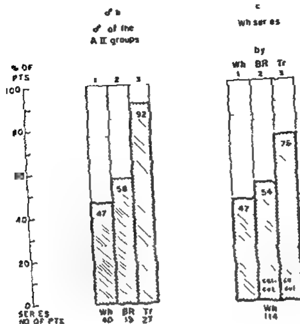

Diagram 14 Radiological results of Wh BR, and Tr treatment in

♂b The prognostically most uniform groups of patients in the 3 series the ♂A II groups. (Results found – statistical assessment cf Diagram 11)

c One series – or 3 identical ones – composed like the Wh series (Results of BR and Tr treatment calculated)

% "SPH"
% "NORM sph"

These two diagrams afford the simplest impression of the relative efficacy of the 3 methods of treatment (A total tabulation of the radiological results is given in the Appendix Table 27)

hand disclosed that the "SPH" percentage was considerably higher with traction than with wheelchair and bed rest treatment. With the use of the *three therapeutic methods* in *one* series composed like the *wheelchair series* the differences were least marked in the total series viz 85 % 82 % and 91 % on wheelchair bed rest and traction respectively. Somewhat greater differences were found on treatment of only the boys of the wheelchair series (82 % 83 % 93 %) and the most marked differences on treatment of the *boys* A_{II} group

77 % 84 % 100 % SPH"

In the last group, the percentage of "SPH" after traction (100 %) was then 30 % higher than after wheelchair treatment (77 %) – a difference which is statistically significant ($P < 0.05$)

All considered, however, the difference between the results as measured by "SPH" is smaller than that measured by "NORM sph"

This is not surprising

If we reduce the demands on a good result to such an extent that they are fulfilled by the majority, possibly all patients of the three series the differences

The fact that the differences observed in the relative efficacy of the treatments is naturally explained by the different nature of the patient groups must strengthen confidence in the present results It demonstrates also that statements concerning efficacy must be accompanied by information as to *which* series they apply For instance, it must be pointed out that in the mixed A_{II} groups the efficacy values apply only to these rather special groups and that the theoretically more reliable values in the boys' A_{II} groups – 47 %, 58 %, and 92 % "NORM sph " after wheelchair, bed rest, and traction respectively – apply only in these even more special groups

Therefore, most interest attaches to the relative efficacy of the three therapeutic methods in each of the three mixed total series – as referred It is in series like these that the treatments should stand their test, and accordingly the results in such series are of direct practical significance

In orthopaedic departments in this country the cases of LCPD referred will be of approximately the same nature with regard to age and stage at institution of treatment as the three series of the present study – in some departments milder like the wheelchair series, in others more severe like the bed rest series

If, in such a department the clientele is known – and it is not likely to change in nature in the near future – it may be predicted, after studying Diagrams 9–10, which results can be obtained by traction and which results are obtainable by wheel chair or by bed rest treatment

Briefly

If the material referred is of the same nature as the present wheelchair series *wheelchair* or *bed rest* therapy will afford about 50 % "good" results ("NORM sph "), *traction* about 75 %

If the materials are of a somewhat heavier nature – like the bed rest or traction series – the results will be somewhat less favourable, but their relative siz will be the same

The concrete values for the three ef ficacies in the wheelchair series are

47 %, 54 %, and 76 % "NORM sph "

on wheelchair, bed rest, and traction treat ment respectively

These values – and the correspondin results in the bed rest and traction series - are the most perspicuous and in practic the most important result of the studies in the preceding radiological sections

With respect to group ' SPH ' it may b added

The size of this group is recorded on al diagrams simultaneously with that o "NORM sph " with a view to the possibili ty of reducing the demands on a goo radiological result, using "SPH " instead o "NORM sph " as a criterion of the percen tage of good results

In the mixed series of different severity as referred, the differences in the results, in terms of the percentage of "SPH " were not marked, in the wheel chair and traction series the results were the same The analyses in the present chapter on more *uniform groups of patients on the othe*

Table 9 Results of treatment of age/stage groups in the BOYS of the wheelchair bed rest and traction series (For No of pts in the groups cf Appendix Table 26)
% = % NORM sph in the groups

All considered however, the difference between the results as measured by "SPH" is smaller than that measured by "NORM sph"

This is not surprising

If we reduce the demands on a good result to such an extent that they are fulfilled by the majority, possibly all patients of the three series the differences

The fact that the differences observed in the relative efficacy of the treatments is naturally explained by the different nature of the patient groups must strengthen confidence in the present results It demonstrates also that statements concerning efficacy must be accompanied by information as to *which* series they apply For instance, it must be pointed out that in the mixed A_{II} groups the efficacy values apply only to these rather special groups and that the theoretically more reliable values in the boys' A_{II} groups – 47 %, 58 %, and 92 % "NORM sph" after wheelchair, bed rest, and traction respectively – apply only in these even more special groups

Therefore, most interest attaches to the relative efficacy of the three therapeutic methods in each of the three mixed total series – as referred It is in series like these that the treatments should stand their test, and accordingly the results in such series are of direct practical significance

In orthopaedic departments in this country the cases of LCPD referred will be of approximately the same nature with regard to age and stage at institution of treatment as the three series of the present study – in some departments milder like the wheelchair series in others more severe like the bed rest series

If, in such a department the clientele is known – and it is not likely to change in nature in the near future – it may be predicted, after studying Diagrams 9–10, which results can be obtained by traction and which results are obtainable by wheel chair or by bed rest treatment

Briefly

If the material referred is of the same nature as the present wheelchair series *wheelchair* or *bed rest* therapy will afford about 50 % "good" results ("NORM sph"), *traction* about 75 %

If the materials are of a somewhat heavier nature – like the bed rest or traction series – the results will be some what less favourable, but their relative size will be the same

The concrete values for the three efficacies in the wheelchair series are

47 % 54 %, and 76 % "NORM sph"

on wheelchair, bed rest, and traction treatment respectively

These values – and the corresponding results in the bed rest and traction series – are the most perspicuous and in practice the most important result of the studies in the preceding radiological sections

With respect to group "SPH" it may be added

The size of this group is recorded on all diagrams simultaneously with that of "NORM sph" with a view to the possibility of reducing the demands on a good radiological result using "SPH" instead of "NORM sph" as a criterion of the percentage of good results

In the mixed series of different severity, as referred, the differences in the results, in terms of the percentage of "SPH" were not marked, in the wheel chair and traction series the results were the same The analyses in the present chapter on more uniform groups of patients on the other

Table 9 Results of treatment of age/stage groups in the BOYS of the wheelchair bed rest and traction series (For No of pts in the groups cf Appendix Table 26)
% – % NORM sph in the groups

Boys / Series treated by	A I	A II	A III	B I	B II	B III
	%	%	%	%	%	%
Wheelchair (93 pts)	81	47 5	0	40	25	0
Bed rest without traction (60 pts)	67	58	37 5	70	37 5	50
Traction in bed (97 pts)	100	92	21	71	56	20

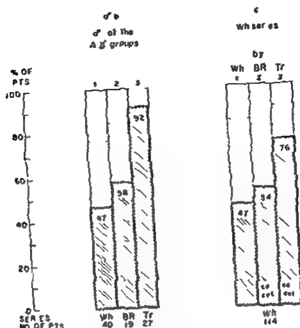

Diagram 14 Radiological results of Wh BR and Tr treatment in

♂b The prognosti cally most uniform groups of patients in the 3 series the ♂A II groups (Results found – statist cal assessment of Diagram 13)

c One series or 3 identical ones composed like the Wh series (Results of BR and Tr treatment calculated)

% SPH
% "NORM sph"

These two diagrams afford the simplest impression of the relative efficacy of the 3 methods of treatment (A total tabulation of the radiological results is given in the Appendix Table 27)

hand disclosed that the SPH percentage was considerably higher with traction than with *wheelchair* and bed rest treatment. With the use of the *three therapeutic methods* in *one* series composed like the *wheelchair* series the differences were least marked in the total series viz 85 %, 82 % and 91 % on wheelchair bed rest and traction respectively. Somewhat greater differences were found on treatment of only the boys of the wheelchair series (82 % 83 % 93 %) and the most marked differences on treatment of the *boys* A_{II} group

77 % 84 % 100 % SPH

In the last group, the percentage of "SPH" after traction (100 %) was then 30 % *higher than after wheelchair treatment* (77 %) – a difference which is statistically significant (P < 0 05)

All considered however the difference between the results as measured by "SPH" is smaller than that measured by "NORM sph"

This is not surprising

If we reduce the demands on a good result to such an extent that they are fulfilled by the majority possibly all patients of the three series the differences

between the results will be slight, possibly 0 The same applies, of course, if stricter demands are made on a good result, so that only a few, perhaps no patients can fulfill them In that case too the difference between the results will be slight, possibly 0.

But if we use a criterion which entails a borderline between satisfactory and unsatisfactory results in the middle of the series — as when using the criterion "NORM sph" — differences, if any, between the results obtained will be most clearly apparent

However, a criterion of a satisfactory radiological result is not set up for the purpose of demonstrating the greatest possible difference between the results obtained, but exclusively with a view to ascertaining whether the *clinical result* corresponding to the radiological criterion is considered satisfactory Above, the radiological criterion "NORM sph" has been maintained as the one which most dependably leads to a satisfactory clinical result In the following clinical sections it will be discussed whether this is too strict and whether the group "SPH" in fact comprises only patients having in practice a good and satisfactory clinical prognosis However, this does not seem likely, considering the appreciable articular deformities in the group (Fig 1)

When using the most reliable radiological criterion of a satisfactory clinical result – the percentage of "NORM sph" – the main result of the radiological sections is (highly simplified)

In groups of patients selected from the three series having the most uniform prognosis, treatment by traction afforded about 80–90 % satisfactory results, bed rest and wheelchair treatment about 50–60 % – according to the nature of the uniform groups

In a series of a composition like e g the wheelchair series it may be predicted that traction will afford about 75 %, bed rest and wheelchair treatment about 50 % satisfactory results

A collected survey of all the radiological results is given in the Appendix Table 27

The group "NORM sph" was singled out from the series by means of three quotients, determined by three measuring methods Therefore, the assessment may be called a "3-quotient assessment" As to the possibilities of using a simpler "1-quotient assessment", based solely upon one measuring method, cf Appendix, Comment 2

B. CLINICAL CONSEQUENCES OF THE RADIOLOGICAL RESULTS

Introduction

The analyses in the present section are based mainly upon reports in the literature – in particular those dealing with follow-up studies of LCPD series and the development of secondary osteoarthritis in general

Unfortunately, the data given in such reports are often incomplete and partly irrelevant with regard to the present problems And – even worse – percentages and other values carry considerable uncertainty They are seldom based upon precise definitions and the substantiation may leave much to be desired

Therefore, the entire present section is interpretable only as *an experiment* – an attempt at giving a picture of the development of secondary osteoarthritis on the basis of the available reports

(Should the result be unsatisfactory, the analyses will at least demonstrate which shortcomings are responsible)

1 Follow-up Findings of Osteoarthritis in LCPD Series

In analysing the late sequelae to LCPD, the first thing to be done is to trace the studies having the longest follow-up period. I succeeded in finding only *5 reports* on follow up studies conducted 25 years or longer after the institution of treatment – and in some cases the onset of the disease (Appendix, Charts 1–2, *age group III*, Nos 1–5)

The follow up period on these cases may seem long – averaging 30–35 years – but nevertheless the patients' mean age at follow-up has been only about 40 years The dispersion is moderate About two-thirds of the patients have usually been 40 years ± 5 – or possibly ± 7 years in series referred during an unusually long period (Danielsson & Hernborg) Thus, it is no great error saying – *for the sake of brevity* – that in these series patient age was around 40

This mean age is unfortunately not as advanced as might be desired. So-called *primary* osteoarthritis in persons with no previous disease of the hips, usually manifests itself by the first symptoms at the age 50–70, rarely before 50, at an average age of about 55–60 (Danielsson *1964* *55* years) Strangely enough, it is usually stated that secondary osteoarthritis – often a sequel to *congenital* articular disease – indeed seems to manifest itself somewhat earlier than the primary type, but rarely more than 5–10 years earlier i e at a mean age of [illegible]

It is [illegible] unfortunate, therefore [illegible] of the patients followed [illegible] 40 In [illegible]

between the results will be slight, possibly 0 The same applies, of course, if stricter demands are made on a good result, so that only a few, perhaps no patients can fulfill them In that case too the difference between the results will be slight, possibly 0

But if we use a criterion which entails a borderline between satisfactory and *unsatisfactory results in the middle of the* series – as when using the criterion "NORM sph" – differences, if any, between the results obtained will be most clearly apparent

However, a criterion of a satisfactory radiological result is not set up for the purpose of demonstrating the greatest possible difference between the results obtained, but exclusively with a view to *ascertaining whether the clinical result* corresponding to the radiological criterion is considered satisfactory Above, the radiological criterion "NORM sph" has been maintained as the one which most dependably leads to a satisfactory clinical result In the following clinical sections it will be discussed whether this is too strict and whether the group "SPH" in fact comprises only patients having in practice a *good and satisfactory clinical prognosis* However, this does not seem likely, considering the appreciable articular deformities in the group (Fig 1)

When using the most reliable radiological criterion of a satisfactory clinical result – the percentage of "NORM sph" – the main result of the radiological sections is (highly simplified)

In groups of patients selected from the *three series as having the most uniform* prognosis, treatment by traction afforded about 80–90 % satisfactory results, bed rest and wheelchair treatment about 50–60 % – according to the nature of the uniform groups

In a series of a composition like e g the wheelchair series it may be predicted that traction will afford about 75 %, bed rest and wheelchair treatment about 50 % *satisfactory results*

A collected survey of all the radiological results is given in the Appendix Table 27

The group "NORM sph" was singled out from the series by means of three quotients, determined by three measuring methods Therefore, the assessment may be called a "3-quotient assessment" As to the possibilities of using a simpler "1-quotient assessment", based solely upon one measuring method, cf Appendix, Comment 2

comprises about 25–50 % of the total patients in a series *If the percentage of* "SPH" *increases* beyond 50 %, the share of "NORM sph" will rise, maybe up to the 100 % found in a normal material If the percentage of "SPH" is below approx 25 %, the share of "NORM sph" drops right down to 0 In a series in which the result is very poor ("SPH" <7–10 %) there will be only cases healing with abnormally shaped femoral heads, viz the *groups* "PATH sph" *and* "NON *sph*" – perhaps *even only cases with irregular*, non spherical heads ("NON sph")

In Helbo's series, in which the group "SPH" made up only 12½ % only five patients had an *epiphyseal* quotient >60, and it is doubtful whether any of these patients had a *joint surface* quotient >85 and a *radius* quotient <115 In other words it is questionable whether this series contained any case of the group "NORM sph"

But when relating the results in the many series to each other, it is of course also of the utmost importance that not *only the* "primary deformities", but also the *concepts* "*radiological osteoarthritis*" and "*clinical symptoms*" have been accurately defined so that we know what we are talking about

Regrettably this wish is rather deficiently fulfilled in the majority of reports The term "radiological osteoarthritis" is defined with some accuracy by only one author (Danielsson) Most authors *seem to take* it for granted that there is general agreement concerning the signs of "radiological osteoarthritis" and this is far from *being* so For instance, Danielsson did not interpret "osteophytes" as a sign of osteoarthritis whereas Wiberg (1939) considers them important *In return*, Wiberg did not consider increased density of skeletal structure as seen in the acetabulum in acetabular dysplasia and subluxation a sign of osteoarthritis, but a reactive skeletal change and thus a precursor of osteoarthritis

The most reliable *radiological* sign of osteoarthritis is probably narrowing of the joint space But even *this is a subject of* discussion, and its frequency is mentioned in only two of the many series *Danielsson* & Hernborg's and Gower & Johnston's.

However, it must be pointed out that all the signs of *radiological osteoarthritis are* objectively *demonstrable* phenomena There may be *disagreement* concerning the significance of the individual components and, in mild cases, about the diagnosis However, when several or all components are present there is usually not any major disagreement about the diagnosis Accordingly, statements about the occurrence of radiological osteoarthritis at follow-up carry considerable objective accuracy

This *applies far less to the clinical manifestations*

"Clinical manifestations" refer, preliminarily, to all clinical symptoms from the hip, whether their cause is primary articular deformity or secondary osteoarthritis

They consist in *objective signs* and *subjective complaints* The former rarely give rise to disagreement On the other hand, assessment of the latter, as indicated by the name, is highly *subjective* What one patient considers a trifle may be a severe complaint to another *Some doctors*, having an optimistic attitude, tend to minimize the patients' complaints, especially when unexplained by objective findings, while others attach much importance to the slightest complaints

This uncertainty is all the more unfortunate as it is the subjective complaints and their *influence upon the patients'* lives that are of most interest in our context

Despite the uncertainty, however, some main features *concerning* the subjective clinical *symptoms* may be deduced from the literature listed *(vide infra)*

The frequency of radiological osteoarthritis as well as of clinical manifestations has usually been stated as the percentage of all patients in the series *This requires a few*

were over 50 (30 in all) In Ratliff's material (5) the oldest patient was 52

On the other hand, there have been many follow-up studies with a shorter follow-up period, a *mean patient age of only 20–25* Seven of these studies are included in the present analysis, because they afford data suited for elucidating the development during the years between primary healing and the age of about 40 (Appendix, Charts 1–2, *age group II*, Nos 6–12)

The state at *primary healing* is elucidated by the three series of the present study, Mose's series that received ambulatory treatment, and another three series from the literature (Charts 1–2, *age group I*, Nos 13–19) This group includes only series in which the radiological deformity was determined *by measurements* on the X-ray films

Thus, the entire analysis comprises 19 series (Numbers and abbreviated names of authors, as listed in the Appendix, Chart 1, will be used below when expedient)

The object of analysing these 19 series is, in brief, to establish the relationship between the radiological joint deformity that the disease has left and the subsequent secondary osteoarthritis – its radiological *signs as well as the clinical symptoms*

But if general conclusions are to be drawn from the analysis of so many series, it is a presupposition that the *primary radiological deformities* of the joint can be described according to the same principles in the different materials, i e so that the results are comparable

To this end, it is essential to determine as far as possible in each series the size of at least one group well-defined with a view to primary radiological deformity If this can be done, the primary radiological deformities in the series may be compared, in broad features

A simple group suited to this purpose is perhaps our *group "SPH"* – which is moreover of particular interest as regards the development of osteoarthritis

The initial task, then, was to try determining the size of this group in the 19 series Of course, this has been possible only with approximation, but nevertheless in a way so that the results seem applicable, as I hope will be apparent from what follows

Most of the *authors* have grouped their series into three, more rarely into four, groups according to the "primary deformity" of the hip joint, as a rule of the femoral head The groups have received different designations Good, fair, poor or – with a view to capital shape "spherical", "flattened", or "irregular" (Appendix, Chart 4) In all late follow-up examinations, these groupings have been based on an estimate, as already mentioned, not upon objective measurements Nevertheless, they have been according to certain criteria described by the authors in the text These descriptions – as well as accompanying X-ray films and drawings, if any – permit a determination of the size of the "SPH" group without too wide a margin of error I have tried to demonstrate this by a more detailed account of the assessment in the 5 series with the longest follow-up (Appendix, Comment 3)

The procedure was the same in series *6–12 with shorter follow up periods*, but a detailed analysis of these series would require too much space

The 7 series used for elucidating the condition at *primary healing* were assessed by *objective measurement* of the articular deformity Therefore the size of the "SPH group can be established with far greater certainty In those series in which Mose's plate was used in the assessment the value is simply given as part of the measuring results

It is not possible to assess the size of the "NORM sph" group in the 16 series from the literature Only it may be said that according to the scanty experience so far of defining this group it makes up about half of the "SPH" group when the latter

comprises about 25–50 % of the total patients in a series If the *percentage of* "SPH " increases beyond 50 %, the *share of* ' NORM sph " will rise, maybe up to the 100 % *found in a normal material* If the percentage of *"SPH "* is *below approx* 25 %, the share of *"NORM sph " drops* right down to 0 In a series *in which* the result is *very poor* ("SPH <7–10 %) there will be only cases healing with abnormally shaped femoral heads, viz the groups PATH sph " and "NON sph " – perhaps even only cases with irregular, non-spherical heads ("NON sph ")

In Helbo's series, in which the group "SPH " made up only 12½ % only five patients had an *epiphyseal quotient* >60, and it is doubtful whether any of these patients had a *joint surface* quotient >85 and a *radius* quotient <115 In other words it is questionable whether this series contained any case of the group "NORM sph "

But when relating the results in the *many series to each other* it is of course also of the utmost importance that not only the primary deformities", but also the concepts *radiological osteoarthritis"* and *clinical symptoms'* have been accurately defined, so that we know what we are talking about

Regrettably, this wish is rather deficiently *fulfilled in the majority of reports* The term "radiological osteoarthritis" is defined with some accuracy by only one author (Danielsson) Most authors seem to take it for granted that there is general agreement concerning the signs of "radiological osteoarthritis" and this is far from being so For instance, Danielsson *did not* interpret "osteophytes" as a *sign of osteo*arthritis whereas Wiberg (1939) considers them important In return, Wiberg did not consider increased density of skeletal structure as seen in the acetabulum in acetabular *dysplasia and subluxation*, a sign of osteoarthritis, *but a reactive* skeletal change and thus a precursor of osteoarthritis

The most reliable *radiological sign* of osteoarthritis is probably *narrowing* of the joint space But even this is a subject of discussion, *and* its frequency is mentioned *in only two of* the many series Danielsson & Hemborg's and Gower & Johnston's

However, it must be pointed out that all the signs of radiological osteoarthritis are objectively demonstrable phenomena There may be disagreement concerning the significance of the individual components and, in mild cases, *about the* diagnosis However, *when several or all components* are present there is usually *not* any major *disagreement about the* diagnosis Accordingly, statements about the occurrence of radiological *osteo*arthritis at follow-up carry considerable objective accuracy

This applies far less to the *clinical manifestations*

"Clinical manifestations" refer, preliminarily, to all clinical symptoms from the hip, whether their *cause is primary articular deformity or secondary osteoarthritis*

They consist *in objective signs* and *subjective complaints* The former rarely give rise to disagreement On the other hand, assessment of the latter, as indicated by the name, is highly subjective What one patient considers a trifle may be a severe complaint to another Some doctors, having an optimistic attitude, tend to minimize the patients' complaints, especially *when* unexplained by objective findings, *while others* attach *much importance* to the slightest complaints

This uncertainty is all the more unfortunate as it is the subjective complaints *and* their influence upon the patients' lives that are of most interest in our context

Despite the uncertainty, however, some *main features* concerning the subjective clinical *symptoms may* be deduced from the literature listed *(vide infra)*

The frequency of radiological osteoarthritis as well as of clinical manifestations has usually been stated as the percentage of all patients in the series This requires a few

comments, considering that one of the objects was to arrive at the proportion of the individual series definitely *without* osteoarthritis.

Most authors have classified their series into groups by first imagining the patients placed in one row according to increasing radiological deformity of the joint This row is then divided into three or four groups, from the least deformed end of the series to the more severely deformed one A statement thereafter that radiological osteoarthritis was present in 50 % of the patients of course does not mean that radiological osteoarthritis occurred exclusively in the most deformed half of the series, in which *all* patients were affected, whereas the remainder were unaffected True, osteoarthritis is bound to be most common at the "most deformed end", but it will extend also into the less deformed end In brief, the cases will spread over a larger part of the series than indicated by the percentage stated This spread has been recorded by the authors of four out of the five series having the longest follow up (Helbo, Sundt, Danielsson & Hernborg, Gower & Johnston) and by some of those with a shorter follow-up, by stating the percentage of radiological osteoarthritis in *each* of the deformity groups In Ratliff's series, and in some series with a shorter follow-up period, I estimated the spread on the basis of other data given by the authors – in particular the size of the deformed groups Of course, such an estimate of the percentage of the series within which the cases of osteoarthritis are spread will be somewhat uncertain For this reason, the estimate was kept at the *lower end* of what is possible and should always be accompanied by the simple percentage of patients with osteoarthritis in the series

The same reasoning applies to stating the percentage of subjective symptoms in the series (cf also Appendix, Comment 4)

These more general remarks on the procedure of the analysis will now be followed by the results

a *Primary Radiological Joint Deformities – in Particular the Percentage of "SPH" – in the 19 Series*

Diagram 15 and Charts 4–5 in the Appendix present my estimate of the sizes of group "SPH." or the measurements of the various authors in the 19 series, related to the authors' classifications The very accurate figures (61 %, 74 %, etc) in the series not measured might lead one to imagine an accuracy which is of course not present The figures are merely a calculative consequence of the various authors' very exact numerical classification which, as already mentioned, carries a great uncertainty Examples of how my figures are derived are given in the Appendix, Comment 3 The figures are of course used only with due regard to their estimative nature Lastly, Chart 3 presents the treatment which had led to these radiological results

On the diagrams and charts the series are then set up in three groups, mainly according to mean age at follow-up

III 40–45 years, II 20–25 years, I <20 years

Within each group the series are arranged by increasing percentage of "SPH ", the lowest at the top

In the lowest group I the percentage of "SPH " in all the series was determined by objective measurements on the X-ray films, in 6 of the 7 series even by the method of Mose In this group, therefore, the percentage of "SPH " can be stated with great accuracy

In the other two age groups the "SPH " percentage has been determined mainly in relation to the authors' estimated classifications and is, therefore, considerably more uncertain than in group I An important goal of the studies is to decide, with the greatest possible accuracy, whether radiological osteoarthritis and subjective complaints occur also in the patients of group "SPH " Therefore, the size of this group

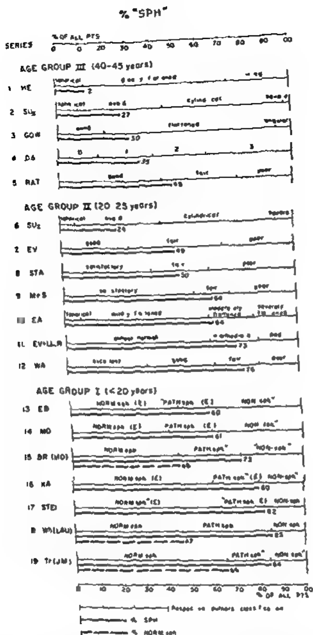

Diagram 15 % "SPH" as estimated by J M – or directly measured – in 19 followed LCPD series listed in relation to the classification used by the respective authors mainly according to the degree of primary radiological deformity

In age groups III and II the classifications are estimated

In age group I the classifications are based on measurements on the X ray films and group SPH appears as a direct link in the measured classification. In this group the terms used by the respective authors are replaced with those used in the present study (pp 20 and 36)

The patients of the respective series are arranged according to increasing radiological deformity from L to R

Appendix, Charts 1–31

comments, considering that one of the objects was to arrive at the proportion of the individual series definitely *without* osteoarthritis

Most authors have classified their series into groups by first imagining the patients placed in one row according to increasing radiological deformity of the joint This row is then divided into three or four groups, from the least deformed end of the series to the more severely deformed one A statement thereafter that radiological osteoarthritis was present in 50 % of the patients of course does not mean that radiological osteoarthritis occurred exclusively in the most deformed half of the series, in which *all* patients were affected, whereas the remainder were unaffected True, osteoarthritis is bound to be most common at the "most deformed end", but it will extend also into the less deformed end In brief, the cases will spread over a larger part of the series than indicated by the percentage stated This spread has been recorded by the authors of four out of the five series having the longest follow-up (Helbo, Sundt, Danielsson & Hernborg, Gower & Johnston) and by some of those with a shorter follow-up, by stating the percentage of radiological osteoarthritis in *each* of the deformity groups In Ratliff's series, and in some series with a shorter follow-up period, I estimated the spread on the basis of other data given by the authors – in particular the size of the deformed groups Of course, such an estimate of the percentage of the series within which the cases of osteoarthritis are spread will be somewhat uncertain For this reason the estimate was kept at the *lower end* of what is possible and should always be accompanied by the simple percentage of patients with osteoarthritis in the series

The same reasoning applies to stating the percentage of subjective symptoms in the series (cf also Appendix, Comment 4)

These more general remarks on the procedure of the analysis will now be followed by the results

a *Primary Radiological Joint Deformities – in Particular the Percentage of 'SPH' – in the 19 Series*

Diagram 15 and Charts 4–5 in the Appendix present my estimate of the sizes of group "SPH" or the measurements of the various authors in the 19 series, related to the authors' classifications The very accurate figures (61 %, 74 %, etc) in the series not measured might lead one to imagine an accuracy which is of course not present The figures are merely a calculative consequence of the various authors' very exact numerical classification which, as already mentioned, carries a great uncertainty Examples of how my figures are derived are given in the Appendix, Comment 3 The figures are of course used only with due regard to their estimative nature *Lastly, Chart 3 presents the treatment* which had led to these radiological results

On the diagrams and charts the series are then set up in three groups, mainly according to mean age at follow-up

III 40–45 years, II 20–25 years, I <20 years

Within each group the series are arranged by increasing percentage of "SPH", the lowest at the top

In the lowest group I the percentage of "SPH" in all the series was determined by objective measurements on the X ray films, in 6 of the 7 series even by the method of Mose In this group, therefore the percentage of "SPH" can be stated with great accuracy

In the other two age groups the "SPH" percentage has been determined mainly in relation to the authors' estimated classifications and is, therefore, considerably more *uncertain than in group I* An important goal of the studies is to decide, with the greatest possible accuracy, whether radiological osteoarthritis and subjective complaints occur also in the patients of group "SPH" Therefore, the size of this group

series, an increasing percentage of "SPH" 19%, 61%, 77%, and 87% with increasingly effective relief from weight-bearing.

The finding of the same relation in the 16 far less elucidated series from the literature must indicate that the estimated "SPH" percentages are credible — *that* they can be regarded as a real expression of the primary deformation of the joint left by the disease in these series

Radiological Osteoarthritis

Despite varying views on the radiological signs of osteoarthritis, the percentage of radiological osteoarthritis in the series must be considered to carry a considerable objective accuracy This is confirmed int al by the development of radiological osteoarthritis *in* the series, from primary healing to the longest follow-up, showing a definite pattern, not characterized by chance

Diagram 16 illustrates the distribution of radiological osteoarthritis *in the series* when arranged by increasing primary radiological deformity (from left to right) The small *circle* signifies the percentage of radiological osteoarthritis in the total series

The pattern evident from Diagram 16 is then

Investigation of the series at *primary healing* or shortly after *(group I)*, revealed no radiological signs of osteoarthritis

At follow-up, at an *age of 20–25 years (group II)*, mild signs of radiological osteoarthritis had started to manifest themselves in a few of the series In others (the youngest two, Nos 8 and 11) such signs are not mentioned, either because they were absent or were deemed of no importance Only one of *these series* (No 6) — that part of Sundt's material which had a follow-up period of <25 years after onset of the disease - exhibited radiological osteoarthritis in quite a number of patients (32%) The explanation *is* that the patients of this *material* had received practically no treatment. Therefore, the disease left primary articular deformities entailing radiological osteoarthritis in an appreciable percentage of the patients as early as the follow-up examination at a mean age of 23 years

Within Sundt's series the percentage of *osteoarthritis* is so high that the cases are distributed all over the group "NON-sph", possibly a little into group "SPH" too. From the viewpoint of osteoarthritis, this series belongs rather to the older age group III

In the other six series of age group II the cases of osteoarthritis were only distributed within the "heavy" part of the "NON-sph" group, viz in the most deformed group of the authors' classification, not occurring at all in group "SPH" The distribution of osteoarthritis in *these series is, broadly* speaking, inversely proportional to the size of group *"SPH"*

The mean age in age group II of these series is 20–25 years, while the *range* is *up to* 30–40 However, there is but little preponderance of radiological osteoarthritis in patients above the mean age

Regrettably, there are no suited materials of a mean age from 25 to 38 years, but when the mean age has reached *40–45 years (age group III)*, the number of cases having *radiological* osteoarthritis has increased so far, that in four of the five *materials they extend also into group "SPH"* In this age group too the distribution is, broadly *speaking*, inversely proportional to the size of group *"SPH"*

As far as may be assessed, the cases of osteoarthritis in "SPH" are localized exclusively *in* "PATH sph" The "NORM sph" group seems to be entirely uninvolved

In other words, the development *of* radiological osteoarthritis *in the 19 materials* is simple and clear From no case at primary healing *to* cases not only in the "NON-sph" group, but also in "SPH" at the latest follow-up examinations (mean

was set at *the lower end* of the inaccuracy range which is always present This may be difficult. For instance, the "SPH" percentage in Evans' and in Gower and Johnston's series has possibly been set too low, but the data from their papers do not permit a higher minimum value Therefore, these two series have to keep their place in the sequence

To ascertain the *age distribution* of the series over the three groups may also be difficult because of incomplete information Besides, the age criterion has deliberately not been strictly observed in some cases

Some of the series in age group I maybe belong to group II (Katz, Steinhauser, Ebach), but were assigned to group I, as the "SPH" percentages in these series – as in the others of group I – have been based *upon objective measurements and therefore* are more reliable than the percentages in group II Reversely, the series of Stamp et al as well as of Evans and Lloyd-Roberts perhaps ought to be transferred from group II to group I, but they are kept in group II because the "SPH" rate is an estimate and therefore a minimum value

On the whole, the grouping of the series in the system was done after thorough reflections and seems to be as reliable as it can be on the basis of the available data

Indeed, this is confirmed by a glance at the treatment used in the various series (Appendix, Chart 3) As a standard of the *efficacy of a treatment one may use* e g that percentage of patients who have been treated by *effective relief from weight bearing*, by ambulatory measures or in hospital (in bed with or without plaster, etc) for 1–2 years, of course with reasonable regard to the treatment in the remainder of the material

If this criterion is applied to the treatments in the various series, the main finding is that the more effective, in the above sense, the treatment has been the higher the rate of "SPH" The lower "SPH" values in age group II, and especially in group III as compared with I, are explicable not only by the figures being minimum values In the main, they are due to less effective treatment in the older series However, the rule concerning the dependence of the "SPH." percentage upon non-weight-bearing does not apply always

For instance, it is surprising, as already mentioned, that the "SPH" rate in Gower & Johnston's series *could hardly* be set higher than 30 % The reason why this is surprising is that in this series the treatment was apparently rather effective – at least long-lasting The explanation is presumably that the series was an *unusually "heavy" one*, i e having an unfavourable prognosis before institution of treatment, many patients being over 8 years of age and arriving late for treatment In Ratliff's series too, a "SPH" rate higher than 48 % would have *been expected considering the rather* effective treatment in the majority of the cases I have been unable to elucidate the cause of this apparent disproportion There have also been several series treated by the *same* method, but obtaining *different* results, e g Evans' and Evans & Lloyd-Roberts' series of in-patients Cause The latter series was *particularly "light"* with respect to the age distribution, *no patient being over 8 years* at the institution of treatment

Different treatments in series of *different* severity may also afford the *same* result in terms of the "SPH" rate This *applies to Lauritzen's "wheelchair series"* and to my traction series However the results prove to differ very much as measured by the percentage of "NORM sph" – and also when *measured by the percentage* of "SPH" when correction is made for the difference in the severity of the series (cf section on radiological assessment)

But on the *whole the rule stands* its test The more patients of the series are treated by long-term effective relief from weight-bearing the higher the "SPH" percentage

This is no *novelty In 1966* the present author found, in four carefully studied

c Clinical Osteoarthritis

But what about the relationschip of radiological osteoarthritis to clinical osteoarthritis?

What does the radiological osteoarthritis mean to the patients?

This question refers exclusively to the symptoms, the purely subjective ones as well as the complaints bound up with the objective signs of disease Objective signs which are not noticed by the patients are of no interest in this connection

The complaints consist in pain, a limp, articular stiffness, limitation of motion, fatigue in the limbs on minor exertion, etc Thereamongst, pain is most apt to be recorded as a complaint at follow up This applies in particular to the *late* follow up studies at which complaints of pain are predominant and therefore receive most attention The other subjective complaints are often not recorded or recorded separately, so that it is impossible to analyse the number of patients having complaints of one kind or another

The symptoms may be due to two causes in part the *primary articular deformity* left by the disease and in part the *subsequent osteoarthritis* It is an experience that pain and articular stiffness are usually late phenomena, occurring in step with the development of radiological osteoarthritis whereas the other complaints are often present immediately after healing, due to the primary joint deformity In most cases however, there is a question of a mixed complex of symptoms whose causes may be difficult to elucidate

In the following analysis *all* subjective symptoms will be recorded, mild as well as severe regardless of their cause – and thereafter it will be attempted to elucidate their causes

However the causes are of less interest than the percentage and the distribution of the symptoms in the series, but even this is considerably more difficult to determine – owing to the subjective nature of the symptoms – than the occurrence of radiological osteoarthritis

Nevertheless, a pattern appears on analysing the subjective symptoms in the series True, it is not as simple as the pattern according to which radiological osteoarthritis develops, but still – a reasonable explanation can be advanced

As in the analysis of radiological osteoarthritis, this pattern is most clearly apparent when the materials are analysed from group I, examined at primary healing, through group II, to group III examined at the mean age of 40

Age Group I

In the introduction it was established that at primary healing the children were largely symptom free This should not be taken quite literally, as in fact there *are* mild complaints In the absence of radiological signs of osteoarthritis at this time, the complaints must be due exclusively to the primary deformity of the joint They consist in a mild limp, fatigue in the leg after walking for rather a long time, etc , but pain is uncommon These complaints will be disclosed by routine history-taking As the children themselves do not attach much importance to them, it seems justified to call the condition "symptom free", at least as a preliminary designation

The reason why these, previously ignored, symptoms are now attributed with essential importance despite their slight intensity is that their extent in the series is possibly interpretable as a *measure of the maximum possible final extent* of secondary osteoarthritis in the series concerned

Indeed, such mild complaints were found among the patients of most group I series

In analysing the "bed rest series" and "traction series" in 1966, I found mild complaints in 22 % of the patients of the bed rest series (Diagram 17, series 15) and in 13 % of the "traction series" These symptoms were spread over *all* radiological

RADIOLOGICAL OSTEOARTHRITIS

age 40–45 years) In the latter group ("SPH ") there are no doubt cases in the most deformed part of the group – "PATH sph " – but presumably none in "NORM sph " The spread of radiological osteoarthritis in the series is broadly speaking, inversely proportional to the size of the "SPH " group

This pattern is very clearly apparent from Diagram 16

c Clinical Osteoarthritis

But what about the relationschip of radiological osteoarthritis to clinical osteoarthritis?

What does the radiological osteoarthritis mean to the patients?

This question refers *exclusively* to the symptoms, the purely subjective ones as well as the complaints bound up with the objective signs of disease. Objective signs which are not noticed by the patients are of no interest in this connection.

The complaints consist in pain, a limp, articular stiffness, limitation of motion, fatigue in the limbs on minor exertion, etc. Thereamongst, pain is most apt to be recorded as a complaint at follow-up. This applies in particular to the *late* follow-up studies at which complaints of pain are predominant and therefore receive most attention. The other subjective complaints are often not recorded or recorded separately, so that it is impossible to analyse the number of patients having complaints of one kind or another.

The symptoms may be due to two causes: in part the *primary articular deformity* left by the disease and in part the *subsequent osteoarthritis*. It is an experience that pain and articular stiffness are usually late phenomena, occurring in step with the development of radiological osteoarthritis, whereas the other complaints are often present immediately after healing, due to the primary joint deformity. In most cases, however, there is a question of a mixed complex of symptoms whose causes may be difficult to elucidate.

In the following analysis *all* subjective symptoms will be recorded, mild as well as severe, regardless of their cause – and thereafter it will be attempted to elucidate their causes.

However, the causes are of less interest than the percentage and the distribution of the symptoms in the series, but even this is *considerably* more difficult to determine – owing to the subjective nature of the symptoms – than the occurrence of radiological osteoarthritis.

Nevertheless, a pattern appears on analysing the subjective symptoms in the series. True, it is not as simple as the pattern according to which radiological osteoarthritis develops, but still – a reasonable explanation can be advanced.

As in the analysis of radiological osteoarthritis, this pattern is most clearly apparent when the materials are analysed from group I, examined at primary healing, through group II, to group III examined at the mean age of 40.

Age Group I

In the introduction it was established that at primary healing the children were largely symptom free. This should not be taken quite literally, as in fact there *are* mild complaints. In the absence of radiological signs of osteoarthritis at this time, the complaints must be due exclusively to the *primary deformity* of the joint. They consist in a mild limp, fatigue in the leg after walking for rather a long time, etc., but pain is uncommon. These complaints will be disclosed by routine history taking. As the children themselves do not attach much importance to them, it seems justified to call the condition "symptom free", at least as a preliminary designation.

The reason why these, previously ignored, symptoms are now attributed with essential importance despite their slight intensity is that their extent in the series is possibly interpretable as a *measure of the maximum possible final extent* of secondary osteoarthritis in the series concerned.

Indeed, such mild complaints were found among the patients of most group I series.

In analysing the "bed rest series" and "traction series" in 1966, I found mild complaints in 22 % of the patients of the bed rest series (Diagram 17, series 15) and in 13 % of the "traction series". These symptoms were spread over *all* radiological

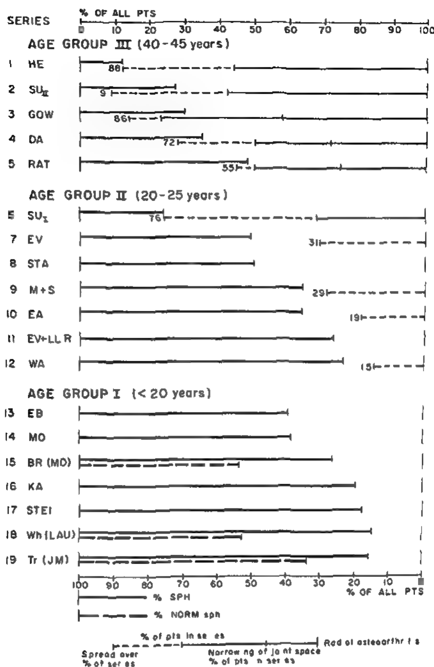

Diagram 16 Radiological osteoarthritis *in 19 LCPD series related to the group "SPH" (and in a few series to "NORM sph")*
Series arranged according to increasing primary radiological joint deformity from L to R
(Magnitude of "spread" apparent from the authors reports directly or indirectly (cf Appendix Comment 4)
Percentages apart from those listed cf Appendix Table 29 Designation of series cf Appendix Chart 1 Number of patients patient age treatment cf Appendix Charts 2–3 Radiological abbreviations and symbols cf ■ 12)

age 40–45 years) In the latter group ("SPH ") there are no doubt cases in the most deformed part of the group – "PATH sph " – but presumably none in "NORM sph " The spread of radiological osteoarthritis in the series is, broadly speaking, inversely proportional to the size of the "SPH " group

This pattern is very clearly apparent from Diagram 16

he two additional years were not analysed In Steinhauer s series *too* (series 17) mild symptoms were reported by 11 % of the patients distributed *over* 29 % of the series and in Ebach s (series 13) in even 32 % of the patients *In Ebach s series it is difficult to ascertain the distribution* but *mild complaints were no doubt also present in the patients of group* SPH

In the other series there were no doubt also mild symptoms scattered over the groups but they have not been recorded as evidently they have been considered of no consequence

In general it may be stated that in four of these seven series analysed at a very early date the authors felt it would be reasonable to record mild symptoms In all series the complaints spread over all radiological groups *also SPH* – in which they were of course rare and slight – occurring even in the group NORM sph *where this group could be defined*

Since as already mentioned radiological osteoarthritis could not be demonstrated in *these series it is reasonable to deduce that these mild complaints have been due exclusively to the joint deformity left by the* disease

Age Group II

In the intermediate age group (group II) there are seven series However one (series 6) differs so much in subjective symptoms from all the others that it has to be treated separately This is perhaps not so surprising as the occurrence of radiological osteoarthritis *in this series was also outside the pattern* which otherwise applied to the group

Accordingly *the following refers only to* the other six series

A higher percentage of patients with symptoms had been recorded in two of the series (Nos 7 and 10) in age group II than in age group I and three series (7 10 and 12) even comprised a small group of patients with fairly severe symptoms (marked x in Diagram 17) The *spread* in the series seems largely to be the same as in group I as all these series too showed symptoms in group SPH , but the symptoms do seem to be more severe

This accentuation of subjective complaints in group II may of course be due to a somewhat less sufficient treatment or to a longer follow up period but the main reason is probably that now we are no longer dealing only with primary deformity complaints

A new element has been added

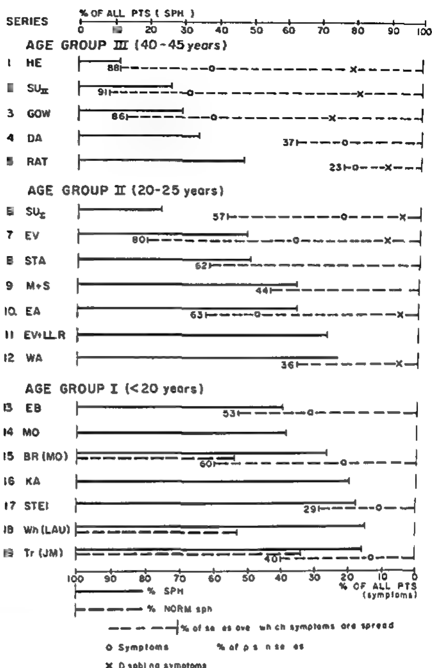
At this early age when the patients averaged only 20–25 years *signs of radiological osteoarthritis* were recorded in four of the six series (Nos 7 9 10 and 12) All were faint and mild signs restricted to the most deformed part of the series and therefore were far from reaching the same extent as the subjective complaints No series had radiological osteoarthritis *in* SPH (Diagram 16)

In other words *the subjective complaints in group II show exactly the same spread* some way into SPH – as in group I *simply because it is still the same* category of complaints that determines the spread the mild deformity complaints But the main explanation why the symptoms have become accentuated in group II (Diagram 17 x) is the radiologically demonstrable incipient osteoarthritis

Thus there are two reasons for the complaints in group II *the joint deformity* and *the osteoarthritis* but the deformity complaints still predominate

However this does not apply to series 6 *(SU I)* In this series the percentage of subjective complaints is all of a sudden strikingly low and scattered over a relatively smaller part of the series than in all the other series in age groups I and II *The complaints do not reach into SPH* This *relatively* favourable finding is all the more striking *as the series* is the most poorly treated one within the groups and has an extensive occurrence of radiological osteo-

CLINICAL SYMPTOMS



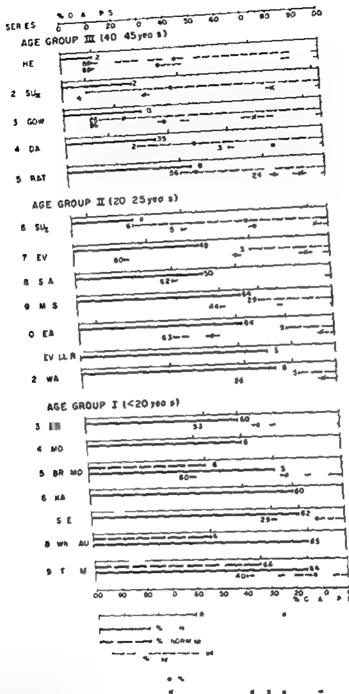


Diagram 17 Clinical symptoms *(cause primary joint deformity or osteoarthritis) in 19 LCPD series set out in relation to the SPH group (or NORM sph)*
Series arranged according to increasing primary radiological joint deformity from L to R

groups – occurring in the traction series even in 4 patients of group "NORM sph" (6 % of the series) The traction series of the present paper (Diagram 17, series 19) is in all essentials identical with that from 1966 only extended by patients admitted in 1962 and 1963 Therefore, subjective symptoms indubitably also occur in the "NORM sph" group of this series, although the symptoms in the patients from

arthritis quite up to group "SPH." – a far greater spread of radiological osteoarthritis than all other series of the group (Diagram 16)

Due to these peculiarities the series most naturally ranges with the lowest materials in group III Therefore, it seems natural to consider it together with the group III series Thereby, the causes of the apparently peculiar pattern are easier to elucidate

Age Group III

The two bottom series of this group (Diagram 17) show exactly the same peculiarities as did series 6 The percentage of patients with complaints and their spread over the series in relation to "SPH" *is strikingly lower* than in all the other series None of the three series showed subjective complaints beyond the most deformed radiological groups This is in surprising contrast to the fact that now *radiological* osteoarthritis has extended to the greater part of the series, right up into group "SPH" (Diagram 16)

The most reasonable explanation of this change in the picture is that now the symptoms of osteoarthritis have increased so in intensity that *they divert attention from the milder primary complaints which have so far predominated* Of course, these mild deformity complaints are still present, but they escape registration – like the mild symptoms of osteoarthritis – as attention is riveted on the more outstanding clinical symptoms of osteoarthritis

The fact that this appears in series 6, despite the shorter follow-up period, is due to the very poor treatment and the consequent, considerable primary articular deformity In series 4 and 5 the treatment had been more effective, but the follow-up period longer – and the result is the same

In the three series at the top (1, 2, and 3) we have got to the stage at which subjective complaints are again recorded in a percentage and extent which is relatively the same as in groups I and II into and up to group "SPH.". (In series 2 a limp was used as a measure of subjective symptoms, if pain is used, the extent is somewhat less, only 73 % of the series, i e up to group "SPH."). However, the intensity of the *symptoms has essentially increased, manifesting* itself in the relatively large groups of fairly severe symptoms in series 1, 2, and 3.

In these series with long follow-up and insufficient treatment, the cases of radiological *osteoarthritis have* evidently developed so far that invariably they give *rise to subjective symptoms of an intensity* great enough to be recorded The milder primary deformity symptoms are no longer recorded

The pattern of the development of subjective symptoms in the 19 series may then be described as follows

In all series, from the shortest to the longest follow-up periods (with three exceptions), there is the same relative extent – spread – of the subjective symptoms in relation to the primary joint deformity They are present in the entire group "NON-sph" and in part of the "SPH" group – i e at least in the group "PATH sph" (Diagram 17)

In age group I (<20 years) the symptoms within the spread range are mild and rare – and caused *exclusively by the primary joint deformity*

In age group II (20–25 years) the intensity of the symptoms within the spread range have increased Now, they are of mixed cause *due partly to the primary joint deformity and partly to incipient osteoarthritis*

Lastly, the symptoms in age group III (40–45 years) are the most intense and the *most dense ones within the spread range* – and they are due *exclusively, or predominantly, to the ever increasing osteoarthritis*

(The reason why three series (4, 5, and 6) apparently fall outside the pattern has been discussed above)

2 Clinical Significance and Calculated Subsequent Development of Osteoarthritis Found in the Series Followed Up

Two problems still await clarification

1 In the above assessment all degrees of severity of radiological and clinical osteoarthritis are included – even the mildest ones. No further evaluation of its clinical importance was carried out *How much does it in fact mean to the patients?*

2 Moreover, the investigations reviewed above suffer from the deficiency that the development of osteoarthritis has never been followed in an LCPD series longer than up to a mean patient age of 40 years What *about the development of the osteoarthritis* beyond this mean age?

An attempt will be made to elucidate these two problems

In the three series that had received the *poorest treatment* (1, 2, 3) radiological and clinical osteoarthritis (of all degrees of *severity*) was present at the mean age of 40 *in* almost two-thirds of the patients – *spread* over almost *9/10* of the series But it was in only just over *1/5 (22 %) of all* the patients that it could be called disabling and at that only to a *moderate* degree All such cases occurred in the group with the most deformed hip joints, *viz* "NON-sph" and in only just over one-quarter (28 %) of the patients in this *group Of all the cases* of osteoarthritis *only one third* (33 7 %) caused symptoms severe enough to be moderately disabling (Diagram 20)

In brief Osteoarthritis was widespread in these series, but *caused* only moderate symptoms

This low intensity *of symptoms* was in *definite contrast* not only to the pronounced radiological signs, but also to the very considerable "primary" joint deformities in *these very series*

This *then* was the appearance of osteoarthritis secondary to LCPD *in the follow up* of patients in the three series when they had reached a *mean* age of 40

It is remarkable that for osteoarthritis secondary to other diseases of the hip, congenital or arising in childhood, the findings are, *in principle*, exactly the same

Jerre has reported a follow-up study of 137 patients with a history of slipped femoral capital epiphysis (in 183 hips) during puberty and treated by various conservative methods (Acta orthop scand suppl 6, 1950)

Follow up at a mean age of 30 showed frequent and extensive radiological osteoarthritis – 75 % spread over 91 % of the series – accompanied by predominantly mild symptoms of *the same extent* Only 23 % of the patients had "disabling" symptoms. This percentage was 22 in the three LCPD series Incidentally, the "disabling" symptoms in Jerre's patients do not seem to have been of serious nature and *were* present chiefly in those with the longest *follow* up (mean age 35 years)

Briefly Exactly the same findings as in the LCPD series – only in patients who were on the average 10 years younger

Jerre concluded "In the present series taken as a whole the discrepancy between the subjective symptoms and the roentgenological arthrosis deformans was *often* remarkably large – – – – – (and) this discrepancy was always in one and the same direction, namely that the roentgenologically *manifest arthrosis* deformans was more severe than was *expected by* the symptoms"

This conclusion, *in its exact* wording, might be drawn from the late *follow-up* studies of *LCPD series* by the three authors (Nos 1, 2, 3 and, with even *greater* justification by Nos 4 and 5)

It may be objected *that it is not permissible to transfer* conclusions from the *nature* and development of *osteoarthritis* secondary to other diseases of the hip during childhood to osteoarthritis following upon LCPD, and that therefore the agreement *found is due to* chance Such scepticism, however, is hardly justified *In reported* studies on the *clinical picture* of secondary

Thus, the *analysis* in this first clinical section — especially of age group III — has confirmed the *preliminary assumption that* signs of osteoarthritis, in particular the most reliable signs, viz radiological osteoarthritis, *develop also in patients in radiological group "SPH "* — at least in group "PATH sph ".

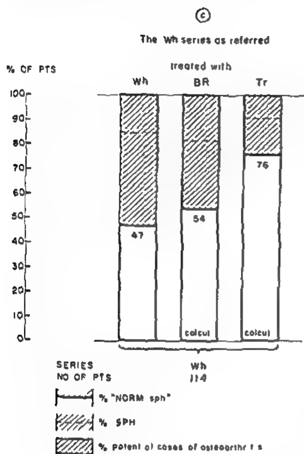

Diagram 19 Extent of potential osteoarthritis in a series composed like the Wh series (114 pts) after 3 possible methods of treatment

(Survey of radiological results (with percentages for SPH) cf Appendix Table 27)

The question now is whether cases of osteoarthritis occur also in "*NORM sph* "

The mild subjective symptoms which appear to be present in this radiological group already at the time of primary healing might be interpreted as a sign that some patients of the group were potential osteoarthritics However, this cannot be confirmed, as the group "NORM sph " cannot be separated in the series in age group III Only, it may be said that in these radiologically so greatly deformed series *the group "NORM sph " must be very small* Therefore, cf Diagram 18, the cases of osteoarthritis will probably not "enter" this group

This can hardly be excluded — but if patients who will escape osteoarthritis are to be picked out at the time of primary healing, there is — according to the findings so far — at least no *major error in selecting the patients* of group *"NORM sph " and in expecting that patients of "PATH sph " and "NON-sph " are potential osteoarthritics*

Should subsequent follow-up studies reveal that all patients of "NORM sph " cannot go on escaping osteoarthritis, the radiological criteria for cases that escape osteoarthritis may easily be restricted

Finally, it may be mentioned that *all* the cases of osteoarthritis observed so far must be designated as secondary, having been demonstrated with certainty only in hip joints deformed by disease

Primary osteoarthritis — by definition — occurs only in previously non-deformed joints and is rarely diagnosed before the age of 50 Above the age of 50 the incidence is low up to an advanced age According to Danielsson, it is only ½ % at 60

But even though there had been a question of persons with previously healthy hips, there would not have been any major possibility of encountering a single case of primary osteoarthritis The number of patients is too small and their age is at most around 40

Diagram 18 (and Appendix Table 29) give a survey of the investigations in the present section Diagram 19 exemplifies the extent of potential cases of osteoarthritis in one series after three possible *methods of* treatment

2 Clinical Significance and Calculated Subsequent Development of Osteoarthritis Found in the Series Followed Up

Two problems still await clarification

1 In the above assessment all degrees of severity of radiological and clinical osteoarthritis are included – even the mildest *ones No further evaluation of its clinical* importance was carried out *How much does it in fact mean to the patients?*

2 Moreover, the investigations reviewed above suffer from the deficiency that the development of osteoarthritis has never been followed in an LCPD series longer than *up to a mean patient age of 40 years* What about the development of the osteoarthritis beyond this mean age?

An attempt will be made to elucidate these two problems.

In the three series that had received the poorest treatment (1, 2 3) radiological and clinical osteoarthritis (of all degrees of severity) was present at the mean age of 40 in almost two-thirds of the patients spread over almost 9/10 of the series But it was in only just over 1/5 (22 %) of all the patients that it could be called disabling and at that only to a moderate degree All *such cases occurred* in the group with the most deformed hip joints, viz "NON-sph" and in only just over one-quarter (28 %) of the patients in this group Of all the cases of osteoarthritis only *one third (33 7 %)* caused symptoms severe enough to be moderately disabling (Diagram 20)

In brief Osteoarthritis was widespread in these series but caused only moderate symptoms

This low intensity of symptoms was in definite contrast not only to the pro nounced radiological signs but also to the very considerable "primary" joint de formities in these *very series*

This then was the appearance of osteoarthritis *secondary to LCPD in* the follow up of patients in the three series when they had reached a mean age of 40

It is remarkable that for osteoarthritis secondary to other diseases of the hip, congenital or arising in childhood, the findings are, in principle, exactly the same

Jerre has reported a follow-up study of 137 patients with a history of slipped femoral capital epiphysis (in 183 hips) during puberty and treated by various conservative methods (Acta orthop scand suppl 6, 1950)

Follow up at a mean age *of 30* showed frequent and extensive radiological osteoarthritis – 75 % spread over 91 % of the series – accompanied by predominantly mild symptoms of *the same extent Only* 23 % of the patients had "disabling" symptoms. This percentage was 22 in the three LCPD series Incidentally, the "disabling" *symptoms in Jerre's patients do not seem* to have been of serious nature and were present chiefly in those with the longest follow up (mean age 35 years)

Briefly Exactly the same findings as in the LCPD series – only in patients who were on the average 10 years younger

Jerre concluded "In the present series taken as a whole the discrepancy between the subjective symptoms and the roentgenological arthrosis deformans was often remarkably large – – – – – (and) *this* discrepancy was always in one and the same direction, namely that the roentgenologically manifest arthrosis deformans *was more severe than was expected* by the symptoms"

This conclusion, in its exact wording, might be drawn from the late follow up studies of LCPD *series by the three authors* (Nos 1 2, 3 and, with even greater justification by Nos 4 and 5)

It *may be objected* that it is not permissible to transfer conclusions from the na ture and development of osteoarthritis secondary to other diseases of the hip during childhood to *osteoarthritis following* upon LCPD, and that therefore the agreement found is due to chance Such scepticism, *however,* is *hardly* justified In reported studies on the clinical *picture of secondary*

DISABLING SYMPTOMS

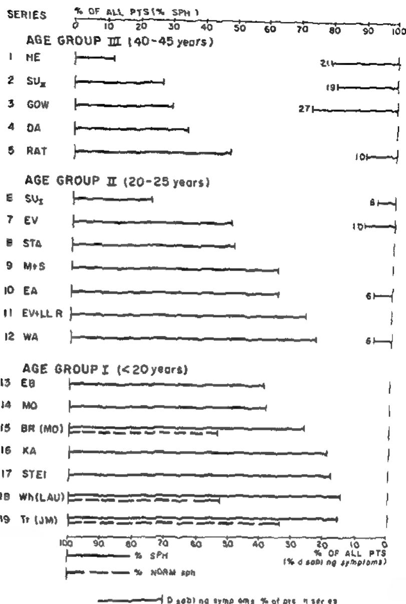

Diagram 20 Disabling symptoms in 19 LCPD series related to the group SPH
The number of cases having disabling symptoms is stated in only 8 of the 19 publications
The series are arranged according to increasing primary radiological joint deformity from I to III
(Percentages apart from those stated cf Appendix Table 29 Designations of series cf Appendix Chart I Abbreviations and symbols cf p 12)

osteoarthritis, this condition is always considered a characteristic disease whose clinical nature and development (qualitatively) are independent of its primary cause Its severity and – to some extent – the time of its onset, on the other hand, depend upon the degree of the primary joint deformity The symptoms set in somewhat earlier and sooner become more marked in the presence of severe joint deformities

However, this of course also applies to osteoarthritis following upon *one* disease which leaves different degrees of articular deformity

In principle, the nature and development of secondary osteoarthritis is the same following different primary causes

Accordingly, Jerre's finding that osteoarthritis secondary to slipped epiphysis is strikingly mild clinically in relation to the

radiological lesions supports the validity of similar findings concerning osteoarthritis following upon LCPD

However, his series was followed up only to a mean age of 30 Therefore, the findings throw no light upon the other problem *The development of secondary osteoarthritis beyond the mean age of 40*

In another study from the literature patients with congenital hip disease were [illegible] at a mean age of *51 years* with [illegible]

with congen[illegible] dysplasia (Wiberg 1939)

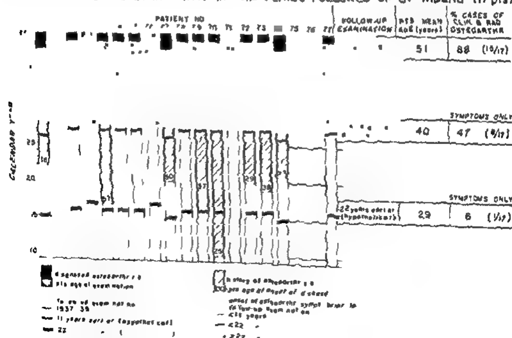
Wiberg's study is better suited for elucidating the further development of osteoarthritis Its main drawback is its small size (*only 17 patients – 14 girls and 3 boys*)

In the files from *two Stockholm hospitals from the period 1908–1925* Wiberg found 44 patients (aged 13–60 years) with definitely diagnosed congenital subluxation (or dysplastic *acetabulum*), *but without signs of osteoarthritis*

In 1937–38 Wiberg wanted to examine these patients to *ascertain whether secondary osteoarthritis had developed.* Regrettably he succeeded in tracing only 16 (to which he added yet another patient in whom the absence of osteoarthritis at primary examination was perhaps in doubt)

At *follow up in 1937–38 – when their mean age was 51 – all 17 patients* had signs of osteoarthritis In two, however, only radiological signs were present, so that they are not included as cases of osteoarthritis In all cases the radiological signs were appreciable, whereas little information is given on the *nature of the clinical manifestations at follow-up – in particular their subjective role.*

Wiberg's 17 patients appear to represent



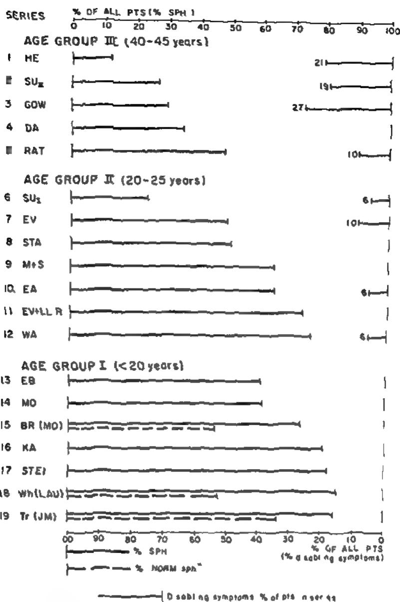


Diagram 21 Development of osteoarthritis in the series followed up by Wiberg (17 pts. with subluxation) The result of the follow up examination performed in 1937–39 and the results which would have been found in two hypothetical follow-up examinations 11 years and 22 years earlier

to R

(Percentages apart from those stated cf Appendix Table 29 Designations of series cf Appendix Chart I Abbreviations and symbols cf p 12)

osteoarthritis, this condition is always considered a characteristic disease whose clinical nature and development (qualitatively) are independent of its primary cause Its severity and – to some extent – the time of its onset, on the other hand, depend upon the degree of the primary joint deformity The symptoms set in somewhat earlier and sooner become more marked in the presence of severe joint deformities However, this of course also applies to osteoarthritis following upon *one* disease which leaves different degrees of articular deformity

In principle, the nature and development of secondary osteoarthritis is the same following different primary causes

Accordingly, Jerre's finding that osteo*arthritis secondary to slipped epiphysis is* strikingly mild clinically in relation to the

in others none (Diagram 21) A continuous distribution and a distinct pattern would require a larger material

Fortunately the literature contains a report on a far larger material from which corresponding information about the development of secondary osteoarthritis may be deduced – even far beyond the mean age of 40

This series *Ruelle s from 1961*, does not afford as many details as Wiberg's, but owing to the far larger number of patients the conclusions carry much greater weight

Ruelle reviewed the records for 271 patients who had consulted a rheumatological clinic in the course of some years for secondary osteoarthritis of the hip due to Slipped epiphysis LCPD, dislocation and subluxation of the hip, etc

For each patient he recorded the onset of what he regarded as clinical symptoms of osteoarthritis Painful limitation of movement in the joint Thereafter, like Wiberg he could tabulate the development of secondary osteoarthritis in his material

This is a study of a nature somewhat different f om those reviewed above which were based upon *a given hip disease* congenital or acquired during childhood, and designed to investigate the development of osteoarthritis after this given disease Ruelle, on the other hand considered the secondary osteoarthritis a well-defined disease entity and regardless of its primary causes he tried to elucidate its development The causes of osteoarthritis in his material then were manifold – mild to severe deformities of the joints left by *different diseases* – and not as in the studies quoted so far deformities after one, well defined hip disease during childhood However the material is so large that Ruelle could divide it up according to the different causes

Still the main advantage of Ruelle's material is its size No other study on secondary osteoarthritis comprises 271 cases

In the material as a whole Ruelle found the values listed in Table 11 and Diagram 22. Unlike the values in Table 10 from Wiberg's study, the osteoarthritis rates do not refer to a *mean age*, but to the rate of osteoarthritis which the patients had developed at the age stated

Ruelle found that about one third (36 %) of the 271 patients developed their subjective symptoms of osteoarthritis before the age of 40 and about two-thirds (70 %) before the age of 50 – i e a duplication of the cases within the decade 40–50

Extracting corresponding values from Wiberg's material shows conformity

Just over one third (35 %) of Wiberg's patients developed symptoms of osteo-

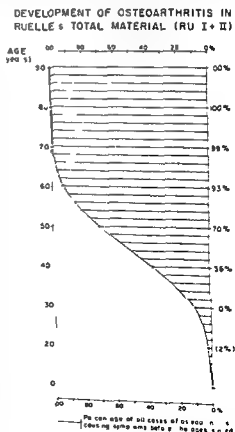

Diagram 22 Development of osteoarthritis in Ruelle s total material (I II) comprising 271 patients.
Graphic presentation of Table 11 (Cf legend of that table)

a "heavy" selection of subluxations As a rule, a large number of such patients escape osteoarthritis (Lance) The explanation is possibly that owing to the low follow-up rate (17/44) he got hold of mainly those patients who had essential complaints on account of their osteoarthritis

At follow-up all the patients were questioned about the *time of onset* of what Wiberg considered subjective clinical symptoms of osteoarthritis Limitation of movement and stiffness in the hip joint with increasing pain All the patients but the two mentioned above were able to state this time with sufficient accuracy

The radiological course is insufficiently elucidated, as the patients had not been X-rayed regularly during the course

Diagram 21 gives the results

The advantage of this diagram is that it affords information about the percentage of osteoarthritis (subj sympt) that would have been found, had the patients been examined *11 years earlier* – i e when they averaged 40 years of age – and if they had been examined *22 years earlier*, i e at a mean age of 29 years

The rate of osteoarthritis is shown in Table 10

Table 10 Series followed up by Wiberg (17 pts) Percentage of clinical osteoarthritis at increasing mean age (subjective symptoms)

Mean age (years)	Percentage of osteoarthritis
51	88 %
40	47 %
29	6 %

Thus, at follow up when the patients' mean age was 40 the osteoarthritis rate (47 %) would have been lower than the mean rate of *all* clinical cases of osteoarthritis in the three LCPD series (64 %), presumably because Wiberg's definition of osteoarthritis is somewhat stricter However, it is of course impossible to tell what the radiological and subjective *severity of*

Table 11 Development of osteoarthritis in Ruelle s total material of secondary osteoarthritis (I +II)

This material comprises 271 patients who applied for treatment of symptoms of secondary osteoarthritis of the hip Here then osteoarthritis means clinical osteoarthritis causing symptoms which have sooner or later reached a severity making the patients present themselves for institutional treatment (cf also text and Appendix Comment 5)

% = The percentage of all cases developing symptoms before the ages stated

(The 5–year values are the result of interpolation between the 10–year values found – or fixed graphically on the basis of Diagrams 22 and 23)

(Detailed list in the Appendix, Table 30)

Age (years)	%
80	100
75	99 5
70	99
65	96
60	93
55	81
50	70
45	53
40	36
35	23
30	10
25	3 (graphic)
20	2 (graphic)

the osteoarthritis was in fact at a mean age of 40

But it is apparent from the diagram that when the patients had grown 11 years older the percentage of osteoarthritis had almost doubled (47 %–88 %)

From our point of view, this is the most important result of Wiberg's study

Whether the clinical severity of the osteoarthritis had increased correspondingly in the course of the 11 years is not directly stated But reading the follow up data on each patient gives an impression of radiological changes which were at that time on the whole severe and clinical symptoms of a nature which must have given rise to considerable complaints

Wiberg's series, however, has the essential drawback of being small For instance the onset of the symptoms is very uneven in the course of the years In some years there had been an accumulation of cases –

gations it was found that *on the whole the development* of secondary osteoarthritis was entirely uniform, regardless of the primary cause Slipped epiphysis, LCPD, subluxation, *congenital* dislocation, acetabular dysplasia, traumas, infection, etc Of course, *the severity of the osteoarthritis may vary*, as after LCPD, but the pattern of its development is in all essentials the same

Therefore, it was attempted to use the values from the material based upon the largest number of patients, and carried up into the oldest age groups, viz Ruelle's, to gain an idea of the further development of osteoarthritis in three of the LCPD series with the longest follow up periods (Helbo's, Gower & Johnston's, and Danielsson & Hernborg's)

However Ruelle's values are not directly applicable to an LCPD series

All patients of Ruelle's series had osteoarthritis (and were presenting themselves for treatment) Thus the osteoarthritis rates at the different ages signify the percentage of the final number *of osteoarthritis* which in Ruelle's material is equal to *the total number of patients*

But if these values are used for determining the osteoarthritis rate in a given LCPD series *at a given time the results* also signify the percentage of the *final number* of cases of osteoarthritis in the series If, for instance it can be predicted that half the patients of the series are likely to escape *osteoarthritis, the calculated rates* have to be divided into half to apply to the total number of patients in the series

When thus applying Ruelle's values to an LCPD series it is therefore of the utmost importance to know the expected final maximum possible – or likely – percentage of osteoarthtitis in the series

It is this maximum possible osteoarthtitis rate which the present author has *tried to establish* in the preceding radiological and clinical sections as apparent from the conclusions at the end of the radiological section and from Diagram 19 At the time of primary healing of an LCPD series the risk of osteoarthritis is present only in patients in deformity groups "PATH sph" and "NON-sph" The size of these groups indicates the maximum part of the series in which *final, full blown osteoarthritis* may occur Osteoarthritis does not necessarily develop in all patients within the range – or in them only – but the deviations are not great (Appendix, Comment 5)

But are we to use the values from Ruelle's *total series of secondary osteoarthritis in the attempt* at calculating the osteoarthritis rate in the LCPD series – or are values from one of his *special subgroups* better suited?

Ruelle divided his material into the following groups according to the primary *causes of the osteoarthritis*

Ru I Deformities of the head-neck following slipped epiphysis, LCPD (only a few), traumas, or infection

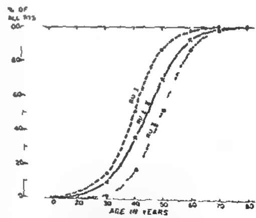

Diagram 23 Development of osteoarthritis in Ruelle's *(RU I) total material of secondary osteoarthritis (I + II) and in two smaller groups of patients (IIc and I) having milder and more severe primary joint deformities.*

The points on the curves indicate the % of all pts. – in the total material or in the special groups – in whom symptoms of osteoarthritis set in before the age stated on the abscissa.

(Percentages and meaning of I + II etc cf Table 12 p 60 For further explanations of this diagram cf also Appendix Comment 5)

arthritis before the 38th year of age (6/17) and almost two-thirds (65 %) before the age of 51 (11/17), i e very close to a duplication during the age 38–51 (The longer interval 38–51 is due to the irregular distribution of the cases in Wiberg's small material)

As to the clinical severity of the osteoarthritis in Ruelle's series we know only that it caused such inconvenience that *sooner or later the patients applied for treatment* No information is given about the radiological development or about the nature of symptoms existing before the patients presented themselves for treatment

But the pattern of development of osteoarthritis in Ruelle's and Wiberg's series is found also in other studies

The mean age at onset of secondary osteoarthritis was 41 years in Wiberg's material, and in Ruelle's it could be calculated to be about 44

In Falconnet and Vignon's series comprising 78 cases of secondary osteoarthritis following subluxation and acetabular dysplasia, the first symptoms of osteoarthritis appeared at the mean age of 44 in the patients with subluxation and at 48 years in those with acetabular dysplasia

In Lloyd-Roberts' series (1955) of 23 cases of severe secondary osteoarthritis requiring operation the first symptoms had appeared at a mean age of 47 In his material of osteoarthritis Danielsson found 18 cases of secondary osteoarthritis of different causes (not subluxation but LCPD, coxa vara etc) These 18 patients had noted the first hip pain at a mean age of 44

Lastly, it has been reported by Lance that osteoarthritis following upon subluxation begins in the late forties at 45–50 years

This is indeed surprising agreement – all the more so as these uniform results have appeared in studies of widely different age groups Wiberg's mean 51 years, Danielsson's 62 years If the spread in the onset of secondary osteoarthritis is no wider than in Ruelle's series – and there is nothing to indicate that it is – these means signify that the onset of secondary osteoarthritis is localized especially, as in Wiberg's and Ruelle's series, within the decade 40–50 years of age

Wiberg, Lance, and others have expressed this briefly by stating that in women secondary osteoarthritis develops during and around the menopause and in men a little later.

Lloyd-Roberts (1955) feels that primary osteoarthritis is "a disease of the aging rather than old age", stating that the symptoms generally set in at the age of 50–55 years, mean 52 5 years, rarely sooner or later Danielsson has reported a mean age of 54 7 years at onset of primary osteoarthritis

However, Lloyd-Roberts' view on primary osteoarthritis as a disease of the aging may evidently be transferred to secondary osteoarthritis – only the latter sets in 5–10 years earlier, at an age of 40–50

Thus, on the basis of a given series of osteoarthritis it was possible to elucidate in retrospect the development of the osteoarthritis (Ruelle)

If we had a corresponding material of osteoarthritis following LCPD, also comprising patients of advanced age, it would be possible to elucidate the development of osteoarthritis following LCPD up to a far advanced age

However, no such material is available at present

The development of osteoarthritis following LCPD might also be elucidated by following a pure LCPD series up through the years This has not so far been done beyond the age of 40

Accordingly there does not seem to be a possibility, at the moment, of completely elucidating the development of osteoarthritis after LCPD

But perhaps there is a way out

In Wiberg's Jerre's, and Ruelle's investi-

gations it was found that on the whole the development of secondary osteoarthritis was entirely uniform, regardless of the primary cause Slipped epiphysis, LCPD, subluxation, congenital dislocation, acetabular dysplasia, traumas, infection, etc Of course, the severity of the osteoarthritis may vary, as after LCPD, but the pattern of its development is in all essentials the same

Therefore, it was attempted to use the values from the material based upon the largest number of patients, and carried up into the oldest age groups, viz Ruelle's, to gain an idea of the further development of osteoarthritis in three of the LCPD series with the longest follow-up periods (Helbo's, Gower & Johnston's, and Danielsson & Hernborg's)

However, Ruelle's values are not directly applicable to an LCPD series

All patients of Ruelle's series had osteoarthritis (and were presenting themselves for treatment) Thus the osteoarthritis rates *at the different ages signify the percentage* of the final number of osteoarthritis which in Ruelle's material is equal to *the total number of patients*

But if these values are used for determining the osteoarthritis rate in a given LCPD series at a given time, the results also signify the percentage of the *final number* of cases of osteoarthritis in the series If, for instance it can be predicted that half the patients of the series are likely to escape osteoarthritis, the calculated rates have to be divided into half to apply to the total number of patients in the series

When thus applying Ruelle's values to an LCPD series, it is therefore of the utmost importance to know the expected final maximum possible — or likely — percentage of osteoarthritis in the series

It is this maximum possible osteoarthritis rate which the present author has tried to establish in the preceding radiological and clinical sections as apparent from the conclusions at the end of the radiological section and from Diagram 19 At the time of primary healing of an LCPD series the risk of osteoarthritis is present only in *patients in deformity groups* "PATH sph" and "NON-sph". The size of these groups indicates the maximum part of the series in which final, full-blown osteoarthritis may occur Osteoarthritis does not necessarily develop in all patients within the range — or in them only — but the deviations are not great (Appendix, Comment 5)

But are we to use the values from Ruelle's *total series* of secondary osteoarthritis in the attempt at calculating the *osteoarthritis rate in the* LCPD series — or are values from one of his *special subgroups* better suited?

Ruelle divided his material into the following groups according to the primary causes of the osteoarthritis

Ru I Deformities of the head-neck following slipped epiphysis, LCPD (only a few), traumas, or infection

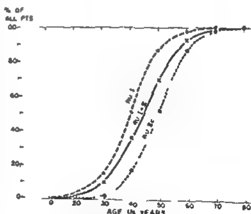

Diagram 23 Development of osteoarthritis in Ruelle's *(RU's) total material of secondary osteoarthritis (I + II) and in two smaller groups of patients (IIc and I) having milder and more severe primary joint deformities.*

The points on the curves indicate the % of all pts. — in the total material or in the special groups — in whom symptoms of osteoarthritis set in before the age stated on the abscissa.

(Percentages and meaning of I + II etc cf Table 12 p 60 For further explanations of this diagram cf also Appendix Comment 5)

arthritis before the 38th year of age (6/17) and almost two-thirds (65 %) before the age of 51 (11/17), i e very close to a duplication during the age 38–51 (The longer interval 38–51 is due to the irregular distribution of the cases in Wiberg's small material)

As to the clinical severity of the osteoarthritis in Ruelle's series we know only that it caused such inconvenience that *sooner or later the patients applied for treatment* No information is given about the radiological development or about the nature of symptoms existing before the patients presented themselves for treatment.

But the pattern of development of osteoarthritis in Ruelle's and Wiberg's series is found also in other studies

The mean age at onset of secondary osteoarthritis was 41 years in Wiberg's material, and in Ruelle's it could be calculated to be about 44

In Falconnet and Vignon's series comprising 78 cases of secondary osteoarthritis following subluxation and acetabular dysplasia, the first symptoms of osteoarthritis appeared at the mean age of 44 in the patients with subluxation and at 48 years in those with acetabular dysplasia

In Lloyd-Roberts' series (1955) of 23 cases of severe secondary osteoarthritis requiring operation the first symptoms had appeared at a mean age of 47 In his material of osteoarthritis Danielsson found 18 cases of secondary osteoarthritis of different causes (not subluxation, but LCPD, coxa vara, etc) These 18 patients had noted the first hip pain at a mean age of 44

Lastly, it has been reported by Lance that osteoarthritis following upon subluxation begins in the late forties at 45–50 years

This is indeed surprising agreement – all the more so as these uniform results have appeared in studies of widely different age groups Wiberg's mean 51 years, Danielsson's 62 years If the spread in the onset of secondary osteoarthritis is no wider than in Ruelle's series – and there is nothing to indicate that it is – these means signify that the onset of secondary osteoarthritis is localized especially, as in Wiberg's and Ruelle's series, within the decade 40–50 years of age

Wiberg, Lance, and others have expressed this briefly by stating that in women secondary osteoarthritis develops during and around the menopause and in men a little later

Lloyd-Roberts (1955) feels that *primary* osteoarthritis is "a disease of the aging, rather than old age", stating that the symptoms generally set in at the age of 50–55 years, mean 52 5 years, rarely sooner or later Danielsson has reported a mean age of 54 7 years at onset of *primary* osteoarthritis

However, Lloyd-Roberts' view on *primary* osteoarthritis as a disease of the aging may evidently be transferred to *secondary* osteoarthritis – only the latter sets in 5–10 years earlier, at an age of 40–50

Thus, on the basis of a given series of osteoarthritis it was possible to elucidate in retrospect the development of the osteoarthritis (Ruelle)

If we had a corresponding material of osteoarthritis following LCPD, also comprising patients of advanced age, it would be possible to elucidate the development of osteoarthritis following LCPD up to a far advanced age

However no such material is available at present

The development of osteoarthritis following LCPD might also be elucidated by following a pure LCPD series up through the years This has not so far been done beyond the age of 40

Accordingly there does not seem to be a possibility, at the moment of completely elucidating the development of osteoarthritis after LCPD

But perhaps there is a way out

In Wiberg's, Jerre's, and Ruelle's investi

gations it was found that on the whole the development of secondary *osteoarthritis* was entirely *uniform*, regardless of the primary cause Slipped epiphysis, LCPD, *subluxation*, congenital dislocation, acetabular dysplasia, traumas, infection, etc Of course, the severity of the osteoarthritis may vary, as after *LCPD*, but the pattern of its development is in all essentials the same

Therefore, it was attempted to use the values *from the material* based upon the *largest number* of patients, and carried up into the oldest age groups, viz Ruelle's, to gain an idea of the further development of osteoarthritis in three of the LCPD series with *the longest follow-up periods* (Helbo's Gower & Johnston's, and Danielsson & Hernborg's)

However Ruelle's values *are not directly applicable* to an LCPD series

All patients of Ruelle's series had osteoarthritis (and were presenting themselves for treatment) Thus the osteoarthritis rates at the different ages signify the percentage of the final number of osteoarthritis which in Ruelle's material is equal to *the total number of patients*

But if these values are used for determining the osteoarthritis rate in a given LCPD series at a given time the results also signify the percentage of the *final number* of cases of osteoarthritis in the series If, for instance it can be predicted that half the patients of the series are likely to escape osteoarthritis the calculated rates have to be divided into half to apply to the total number of patients in the series

When thus applying Ruelle's values to an LCPD series *it is therefore of the utmost importance to know the expected final* maximum possible – or likely percentage of osteoarthritis in the series

It is this maximum possible osteoarthritis rate which the present author has tried to establish in the preceding radiological and clinical sections as apparent from the conclusions at the end of the radiological section and from Diagram 19 At the time of primary healing of an LCPD series the risk of osteoarthritis is present only in patients in deformity groups "PATH sph" and "NON-sph" The size of these groups *indicates* the maximum part of the series in *which final, full blown* osteoarthritis may occur Osteoarthritis does not necessarily *develop* in all patients within the range – *or in them only* – but the deviations are not great (*Appendix*, Comment 5)

But are we *to use the values* from Ruelle's *total series* of secondary osteoarthritis in the attempt at calculating the osteoarthritis rate in the LCPD series – or are values from one of his *special subgroups* better suited?

Ruelle divided his material into the following groups according to the primary causes of the osteoarthritis

Ru I Deformities of the head neck following slipped epiphysis, LCPD (only a few), traumas, or infection

DEVELOPMENT OF OSTEOARTHRITIS IN RUELLE'S TOTAL MATERIAL (I+II) AND IN TWO SMALLER GROUPS OF PATIENTS (I AND IIc)

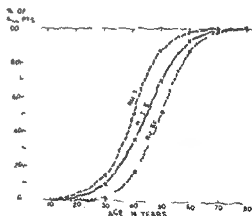

Diagram 23 Development of osteoarthritis in Ruelle's (RU's) total material of secondary osteoarthritis (I + II) and in two smaller groups of patients (IIc and I) having milder and more severe primary joint deformities.

The points on the curves indicate the % of all pts in the total material or in the special groups in whom symptoms of osteoarthritis set in before the age stated on the abscissa.

(Percentages and meaning of I + II etc cf Table 1, p 60 For further explanations of this diagram cf also Appendix Comment 5)

Table 12 Development of osteoarthritis in Ruelle's total series (designated I + II) and in the special groups of patients I, II a, II b + c, II c
% = Percentage of all cases of osteoarthritis – in the total material and in the various groups of patients – causing symptoms before the ages stated
As to the designation osteoarthritis, cf Appendix, Comment 5

	Total material	*Groups* Sites of joint deformities			
		Head/neck	Acetabulum		
			Congen disloc	Sublux. and acetabular dysplasia	Acetabular dysplasia
Ruelle's designation	I + II	I	II a	II b + c	II c
No of pts.	271	68	38	165	120
Age (years)	%	%	%	%	%
80	100			100	100
70	99	100		99	98
60	93	98	100	89	87
50	70	87	90	59	52
40	36	51	58	24	17
30	10	15	21	6	2
Degree of deformity	Moderate	Fairly severe	Most severe	Fairly mild	Mildest

Ru II Acetabular deformities left by (a) congenital dislocation, (b) subluxation, (c) acetabular dysplasia

True, group I does contain cases of LCPD, but apparently few – and the group is incidentally of an extremely mixed nature

The group II cases clearly differ in essence from LCPD

In these different groups the osteoarthritis develops according to the same fundamental pattern (Diagram 23, Table 12)

In the total material (I + II) the development of osteoarthritis gradually starts at the age of 30, but does not really gain impetus until the decade 40–50 years, thereafter, the tempo slows down towards the age of 60 (cf also Diagram 22) In the groups with the most severely deformed joints (e g I) the development is under way already at the age of 30, while in groups with less deformed joints (II c) it does not start until the age of 40, but then continues at an undiminished rate until the age of 60

When considering the groups together, the development of osteoarthritis takes place between the ages of 30 and 60, and a particularly rapid rate between 40 and 50 is common to all groups

As it is difficult to assess the relation between the severity of the articular deformities in Ruelle's groups and in the *LCPD* series with late follow-up, the osteoarthritis rate for Ruelle's *total material* will be used, for the time being, for calculating the expected rate of osteoarthritis in the LCPD series

Thereby it is possible to base the calculation upon the largest possible number of patients – and to attain the greatest possible certainty

The procedure is as follows

First, the osteoarthritis rate in the LCPD series is calculated at the time of follow-up – and this calculated value is then compared with that *found*

If this form of calculation proves satisfactory, it will be used to form an impression of the expected development of osteoarthritis beyond the time of follow up

This may be exemplified by a brief description of the calculation in the series followed up by Helbo

In his series the patients (47) were distributed at follow up on the age groups shown in Table 13

Table 13 Age distribution in Helbo's series at follow-up Mean age 42 years.

Age groups (years)	No of pts.
50 60	5
40–50	24
30–40	18

First the calculation in the age group 40–50 years

If the age of all 24 patients in this group is just over 40 the expected osteoarthritis rate in the group will correspond approximately to Ruelle's rate at 40 36 % (Tables 11 and 12) But if the majority are closer to 50 the osteoarthritis rate in the group will correspond approximately to Ruelle's rate at 50 70 % As a rule and especially in the middle groups the patients are evenly distributed over the age range 40–50 years and if so the osteoarthritis rate in this age group corresponds approximately to the mean of Ruelle's rates at 40 and 50, i e the osteoarthritis rate at 45 is 53 % (In the extreme groups under 30 and over 60 the mean value has to be corrected a bit (shown graphically in Diagram 23))

According to Ruelle's values then one would expect finding in the age group 40 50 years $\frac{24 \times 53}{100}$ = 13 patients with osteoarthritis

A similar calculation may be performed in the other age groups Addition will show that of all 47 patients of the material 21 will – according to Ruelle – have subjective symptoms of osteoarthritis at the time of follow up, i e about 45 %

However, the presupposition that this value is correct is that *all* patients of Helbo's series are potential osteoarthritics – and they are presumably not According to the review of the literature in the preceding section, etc , it is predominantly likely that the patients of the primary radiological group "NORM sph " will escape osteoarthritis – whereas all patients of the other groups are at risk Therefore, the percentage size of these groups combined ("PATH sph " + "NON-sph ") ought to indicate the maximum rate of osteoarthritis in the material

But in Helbo's series – and the other series followed up – the size of the group "NORM sph " cannot be definitely ascertained Therefore, that part of the series in which there is a risk of osteoarthritis cannot be definitely singled out However, major errors are not made – at least not in series having small "SPH " groups – by fixing the size of the part risking osteoarthritis by an estimated division of group "SPH ", int al with regard to any spread of osteoarthritic symptoms into this group as *found at follow up* (cf e g Gower & Johnston's series)

In Helbo's series however, the size of group "NORM sph " may be estimated with somewhat greater accuracy, as he had measured epiphyseal quotients On that basis the groups "PATH sph " + "NON-sph " were estimated at 95 % Accordingly, the expected rate of osteoarthritis at follow up is $\frac{45 \times 95}{100}$ = 41 %

Similar calculations may be carried out in Gower & Johnston's and in Danielsson & Hernborg's materials but not in Sundt's (II) and Ratliff's as the age distribution at follow up is not stated

The results are shown in Table 14

It is a common feature to all patients of Ruelle's series that sooner or later after onset of symptoms they *applied for treatment* in a "rheumatic" clinic

Table 12 *Development of osteoarthritis in Ruelle's total series (designated I + II) and in the special groups of patients I, II a, II b + c, II c*

% = Percentage of all cases of osteoarthritis – in the total material and in the various groups of patients – causing symptoms before the ages stated

As to the designation osteoarthritis, cf Appendix, Comment 5

	Total material	Groups			
		Sites of joint deformities			
		Head/neck	Acetabulum		
			Congen disloc	Sublux and acetabular dysplasia	Acetabular dysplasia
Ruelle's designation	I + II	I	II a	II b + c	II c
No of pts	271	68	38	165	120
Age (years)	%	%	%	%	%
80	100			100	100
70	99	100		[illegible]	98
60	93	98	100	89	87
50	70	87	90	59	52
40	36	51	58	24	17
30	10	15	21	6	2
Degree of deformity	Moderate	Fairly severe	Most severe	Fairly mild	Mildest

Ru II Acetabular deformities left by (a) congenital dislocation, (b) subluxation, (c) acetabular dysplasia

True, group I does contain cases of LCPD, but apparently few – and the group is incidentally of an extremely mixed nature

The group II cases clearly differ in essence from LCPD

In these different groups the osteoarthritis develops according to the same fundamental pattern (Diagram 23, Table 12)

In the total material (I + II) the development of osteoarthritis gradually starts at the age of 30, but does not really gain impetus until the decade 40–50 years, thereafter, the tempo slows down towards the age of 60 (cf also Diagram 22) In the groups with the most severely deformed joints (e g I) the development is under way already at the age of 30, while in groups with less deformed joints (II c) it does not start until the age of 40, but then continues at an undiminished rate until the age of 60

When considering the groups together, the development of osteoarthritis takes place between the ages of 30 and 60, and a *particularly rapid rate between 40 and 50* is common to all groups

As it is difficult to assess the relation between the severity of the articular deformities in Ruelle's groups and in the LCPD series with late follow-up, the osteoarthritis rate for Ruelle's *total material* will be used, for the time being, for calculating the expected rate of osteoarthritis in the *LCPD* series

Thereby it is possible to base the calculation upon the largest possible number of patients – and *to attain* the greatest possible certainty

The procedure is as follows

First, the osteoarthritis rate in the LCPD series is calculated at the time of follow-up – and this calculated value is then compared with that *found*

If this form of calculation proves satisfactory, it will be used to form an impression of the *expected development* of osteoarthritis beyond the time of follow up

This may be exemplified by a brief description of the calculation in the series followed up by Helbo

In his series the patients (47) were distributed at follow up on the age groups shown in Table 13

Table 13 Age distribution in Helbo's series at follow-up Mean age 42 years.

Age groups (years)	No of pts.
50–60	5
40 50	24
30–40	18

First the calculation in the age group 40–50 years

If the age of all 24 patients in this group is just over 40 the expected osteoarthritis rate in the group will correspond approximately to Ruelle's rate at 40 36 % (Tables 11 and 12) But if the *majority* are *closer* to 50 the *osteoarthritis* rate in the group will correspond approximately to Ruelle's rate at 50 70 % As a rule, and especially in the middle groups, the patients are evenly distributed over the age range 40–50 years, and if so the osteoarthritis rate in this age group corresponds approximately to the mean of Ruelle's rates at 40 and 50 i e the osteoarthritis rate at 45 is 53 % (In the extreme groups under 30 and over 60 the mean value has to be corrected a bit (shown graphically in Diagram 23))

According to Ruelle's values then, one would expect finding in the age group 40–50 years $\frac{24 \times 53}{100} = 13$ patients with osteoarthritis

A similar calculation may be performed in the other age groups Addition will show that of all 47 patients of the material 21 will – according to Ruelle – have subjective symptoms of osteoarthritis at the time of follow up, i e about 45 %

However, the presupposition that this value is correct is that *all* patients of Helbo's series are potential osteoarthritics – and they are presumably not According to the review of the *literature* in the preceding section, etc , it is predominantly likely that the patients of the primary radiological group "NORM sph " will escape osteoarthritis – whereas all patients of the other groups are at risk Therefore, the percentage size of these groups combined ("PATH sph " + "NON-sph ") ought to indicate the maximum rate of osteoarthritis in the material

But in Helbo's series – and the other series followed up – the size of the group "NORM sph " cannot be definitely ascertained Therefore, that part of the series in which there is a risk of osteoarthritis cannot be definitely singled out However, major errors are not made – at least not in series having small "SPH " groups – by fixing the size of the part risking osteoarthritis by an estimated division of group "SPH " int al with regard to any spread of osteoarthritic symptoms into this group as *found at follow up* (cf e g Gower & Johnston's series)

In Helbo's series, however, the size of group "NORM sph " may be estimated with somewhat greater accuracy, as he had measured epiphyseal quotients On that basis the groups "PATH sph " + "NON-sph " were estimated at 95 % Accordingly, the expected rate of osteoarthritis at follow-up is $\frac{45 \times 95}{100} = 41$ %

Similar calculations may be carried out in Gower & Johnston's and in Danielsson & Hernborg's materials, but not in Sundt's (II) and Ratliff's, as the age distribution at follow up is not stated

The results are shown in Table 14

It is a common feature to all patients of Ruelle's series that sooner or later after onset of symptoms they *applied for treatment* in a "rheumatic" clinic

Table 14 Percentage of osteoarthritis calculated and found at the time of the latest follow-up examination in the series of Helbo Gower & Johnston, and Danielsson & Hernborg

Values calculated on the basis of those in Ruelle's total material (I + II), the maximum possible osteoarthritis rate being fixed as 95 % in Helbo s series 86 % in Gower & Johnston s, and 72 % in Danielsson & Hernborg s

HE + GOW + DA	39 6				

The values in Ruelle's analysis (Table 11) are based upon data concerning the *time of onset of the symptoms*, but in the summation groups used in the calculation – patients developing osteoarthritis prior to the age of 30, 40, 50, etc – the symptoms must have started in most cases many years earlier Therefore, the majority of patients in the groups have applied for treatment long ago In only a small number of cases the symptoms have set in a short time before the ages for which the osteoarthritis rates were calculated, so that at that time the patients have not yet applied for treatment Regrettably, Ruelle does not give any data regarding the interval between the onset of symptoms and the presentation for treatment

In fact, therefore, the values in Ruelle's analysis concern patients *the majority of whom had applied for treatment* because *they felt* that their symptoms *required treatment*

Thus, if values from Ruelle's material are used for calculating the osteoarthritis rate in a given LCPD series at a given time, the calculated rate will *express mainly the percentage of patients who had applied for treatment* – i e patients with "treatment-requiring" osteoarthritis *in the sense stated* But as the calculated percentage will include a small number of patients who have not yet applied for treatment, it must be expected to be a little higher than the actual percentage of patients who have applied for treatment

In the above analyses of osteoarthritic symptoms found at follow-up in various materials, all, even the mildest, symptoms recorded have been included Therefore, the stated rate of osteoarthritis is a maximum

From among these cases we can now (possibly) single out a smaller group of patients who had applied for treatment (having "treatment requiring osteo arthritis") and from among them an even smaller group with "disabling" osteoarthritis

In other words the percentage of patients who had applied for treatment will be between that of patients with "disabling" osteoarthritis and that of all recorded cases

From Table 14 it may be seen that if the values from Ruelle's total series are applied to Helbo's and Gower and Johnston's, the *calculated* percentages *fit the found* ones well

In both series the calculated rate of osteoarthritis is between that of "disabling" osteoarthritis and all recorded cases of osteoarthritis

Helbo even recorded a rate of "treatment requiring" osteoarthritis (corresponding to our term) which is exactly where *it would be expected* a little lower *than the calculated rate, viz* 34 % as compared with 41 %

In Danielsson's and Hernborg's series it is difficult to compare the calculated and found values, because evidently Danielsson's evaluation of the symptoms differs from that in other materials (Diagram 17)

For instance, Danielsson and Hernborg's *percentage of all clinical cases* of osteoarthritis (including a limp 23 %) seems to correspond largely to Helbo's percentage of "treatment requiring" osteoarthritis (cf Appendix, Comment 5) – and his percentage of patients with "more troublesome symptoms" to Helbo's and Gower & Johnston's percentage of patients with "disabling" symptoms

When this is taken into consideration, the calculated osteoarthritis rate (28 %) is in reasonable conformity with the findings in the other two series

From the agreement between the calculated and found values in Helbo's and Gower & Johnston's *series it is apparent* that in fact the development of osteoarthritis in their series has been like that in Ruelle's *total material* of secondary osteoarthritis

But if we apply values from Ruelle's *more severe groups* (e g group I) to Helbo s and Gower & Johnston's *series, we* get calculated rates of osteoarthritis *too high* in relation to those found The fact is that in these groups the development of osteoarthritis starts earlier In the "*mild*" *groups* (e g *II c*) *the* osteoarthritis develops later – and the use of values from these groups will make the calculated osteoarthritis rates *too low*.

It is a presupposition for the above calculation that the patients' age distribution at follow up is known *Only then* can the expected rate of osteoarthritis be calculated on the basis of Ruelle's values If we know the age distribution in the materials at follow up, we *also know the age* distribution at *any time before and after* (normal mortality does *not* essentially alter *the age distribution*) – and it ought to be easy to calculate the rate of osteoarthritis expected, according to Ruelle, at any time

This involves int al the possibility of calculating the *future* development of osteoarthritis in the three series with reasonable accuracy When calculation of the osteoarthritis rate in the series, more than 25 years after onset of the disease, fits the actual one so relatively well, calculation of the future osteoarthritis rate ought to show reasonable agreement with the development of osteoarthritis which is going to take place

Therefore, such a calculation will be attempted

The procedure is as follows – using Helbo's follow up series as an example

The age distribution in Helbo's series at follow-up was as shown in Table 13 When adding 10 years to the age groups we get the age distribution in the material *10 years after the follow-up* (Table 15)

By means of Ruelle's values, the rate of *osteoarthritis at this time may now be* calculated as described for Helbo's series at follow up

Table 15 Age distribution in Helbo's series 10 years after the follow-up examination.

Age groups (years)	No of pts.
60–70	5
50–60	24
40–50	18

Table 14 Percentage of osteoarthritis, calculated and found at the time of the latest follow-up examination in the series of Helbo, Gower & Johnston, and Danielsson & Hernborg

Values calculated on the basis of those in Ruelle's total material (I + II), the maximum possible osteoarthritis rate being fixed as 95 % in Helbo s series 86 % in Gower & Johnston s and 72 % in Danielsson & Hernborg's.

Johnston s and in Danielsson & Hemborg's series may be calculated

The total result of the calculations in all *three series may be seen in Table 17*

Thus if the follow up is repeated 10 *years after that which has been performed* – when the patients have attained a mean age of 50–55 years – the percentage of patients who had applied for treatment of osteoarthritis in Helbo's and in Gower & Johnston's series must be expected to have increased from about 40 % at a mean age of 40–45 years, to about 65 % – or to almost *two-thirds of the patients* – in Danielsson & Hemborg's material presumably to one-half

The development of osteoarthritis does not approach its maximum until the patients have attained the mean age of 60–65 at follow up 20 years later At follow up at *a mean age of 70–75 years* the percentage of osteoarthritis has increased only slightly from the age of 60–65

In other words The follow up examinations by the various authors have disclosed

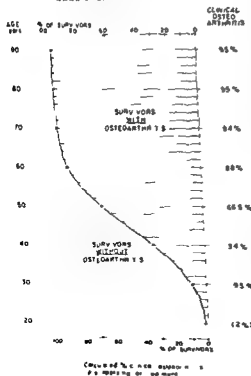

Diagram 25 Development of clinical osteoarthritis (pts. applying for treatm) in Helbo s series, calculated by using f gures from Ruelle s total material (I + II) the maximum possible osteoarthritis rate in the series being fixed at 95 %

The percentages signify % osteoarthritis among survivors at the ages stated

These values do not correspond quite to those in Table 16 as the osteoarthritis rates on this diagram are birth date values i.e the osteoarthritis rate when the patients pass the stated birthdays whereas the values in the table are the osteoarthritis rate when the mean age in the series is as stated

Calculation of the birth date values affords a possibility of a combination with the mortality curve as visualized in Diagram 26

Table 16 Calculated development of clinical osteoarthritis presented for treatment from 1930 to 1980 in the series followed up by Helbo and the percentage found at Helbo s follow up examination in 1950

Presented for treatm   Osteoarthritis in patients who have applied for physiotherapy orthopaedic treatment radiotherapy, or the like

The calculations were done using values from Ruelle s total material (I + II) Starting from the number and age distribution of the patients seen at follow up in 1950 they were carried out at 10-year intervals before and after the follow-up examination

The calculated percentages are equal to the osteoarthritis rate in patients surviving at the times stated (cf Appendix Comment 5)

The maximum possible osteoarthritis rate in the series is fixed at 95 % (Appendix, Comment 5)

Mean age	Calendar year	Clinical osteoarthritis in Helbo's series (I–HE)			
		Found	Calculated	Found	Found
		All cases of clinical osteoarthritis	Presented for treatment	Presented for treatment	Disabling osteoarthritis
		%	%	%	%
72 years	1980		93		
62	1970		85		
52	1960		67		
42	1950	62	41	34	21
32	1940		18		
22	1930		6		

Corresponding calculations may be carried out 20 years, 30 years, etc after follow-up – and also 10 and 20 years before

The role of *normal mortality* in the older age groups may be taken into consideration – but it has proved of no major importance owing to the moderate age scatter in the materials

The result is given in Table 16 and Diagram 24

Diagram 24 Calculated development of clinical osteoarthritis (pts applying for treatm) in Helbo s follow up series (I HE) performed by using figures from Ruelle s total material (I + II)

% – % of survivors at the times stated (with corresponding mean ages)

The % of osteoarthritis found at Helbo s follow up examination in 1950 is also listed (+ % radiol osteo arthr)

In other words the diagram is in all essentials a graphic presentation of Table 16 (cf legend of that table)

It will be seen that the % of clinical osteoarthritis (pts applying for treatm) calculated for 1950   41 %   is as expected somewhat higher than that found – 34 % (because the calculated percentage comprises a small number of patients who had not yet applied for treatment)

In exactly the same way, the future development of osteoarthritis in Gower &

DEVELOPMENT OF OSTEOARTHRITIS IN HELBO's SERIES (I HE)

% = % of clinical osteoarthritis in the survivors at the [illegible] osteoarthritis rates HE 95 %, GOW 86 %, DA 72 %.

	Calculated percentage of patients who have applied for treatment with symptoms of osteoarthritis					
	HE		GOW		DA	
	%	Mean age (years)	%	Mean age (years)	%	Mean age (years)
30 years later	93	72	85	75	69	71
20 years later	85	62	80	65	61	61
10 years later	67	52	65	55	46	51
At latest follow up examination	41	42	42	45	28	41

Johnston's and in Danielsson & Hernborg's series may be calculated

The total result of the calculations in all three series may be seen in Table 17

Thus, if the follow up is repeated 10 years after that which has been performed – when the patients have attained a mean age of 50–55 years – the percentage of patients who had applied for treatment of osteoarthritis in Helbo's and in Gower & Johnston's series must be expected to have increased from about 40 % at a mean age of 40–45 years, to about 65 % – or to almost two-thirds of the patients – in Danielsson & Hernborg's material presumably to one half

The development of osteoarthritis does not approach its maximum until the patients have attained the mean age of 60–65 at follow up 20 years later At follow up at a mean age of 70–75 years the percentage of osteoarthritis has increased only slightly from the age of 60 65

In other words The follow up examinations by the various authors have disclosed

DEVELOPMENT OF OSTEOARTHRITIS IN HELBO's SERIES (I HE)

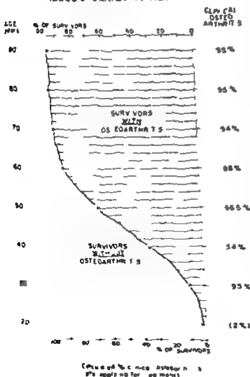

Diagram 25 Development of clinical osteoarthritis (pts. applying for treatm) in Helbo's series calculated by using figures from Ruelle's total material (I + II) the maximum possible osteoarthritis rate in the series being fixed at 95 %.

The percentages signify % osteoarthritis among survivors at the ages stated

These values do not correspond quite to those in Table [illegible] as the osteoarthritis rates on this diagram are birth date values i.e. the osteoarthritis rate when the patients pass the stated birthdays whereas the values in the table are the osteoarthritis rate when the mean age in the series is as stated.

Calculation of the birth date values affords a possibility of a combination with the mortality curve as visualized in Diagram 26

only half the patients applying for treatment of osteoarthritis who will be found at a follow-up examination at a mean age of about 60

The calculated percentages express the number of cases of osteoarthritis in per cent of survivors (cf Appendix, Comment 5)

If the number of cases of osteoarthritis in survivors is to be expressed as the percentage of the original number of patients in a series, the mortality has to be taken into consideration (cf Diagrams 25 and 26)

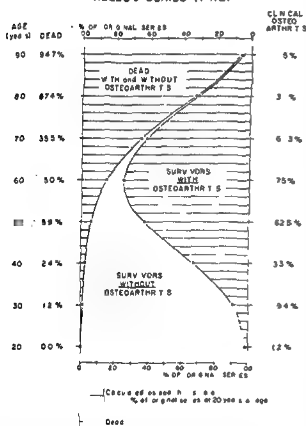

Diagram 26. Development of clinical osteoarthritis (pts applying for treatm) in Helbo s series calculated by using figures from Ruelle s total material (I + II) the maximum possible osteoarthritis rate being fixed at 95 %.

The calculated osteoarthritis rates signify osteoarthritis in the survivors when they pass the birthdays stated expressed as % of the original series *i e the number of patients at 20 years of age – not as in Diagram 25 as* % of survivors

(Mortality curve in relation to 20 years of age Statistisk Årbog Denmark 1968 As to the use of Ruelle s figures cf Appendix Comment 5)

3 Calculated Clinical Long-term Prognosis for the Three Series Not Yet Followed Beyond Primary Radiological Healing Wheelchair, Bed Rest, and Traction Series

When the future rate of osteoarthritis in the LCPD series with late follow up can be calculated, it is of course also possible to calculate the subsequent development of osteoarthritis in the LCPD series treated in the 50's and 60's and only followed up to the time of primary healing – viz the wheelchair, bed rest, and traction series

The only condition ■ to know – as in the series seen at follow up – the age distribution in one given calendar year after primary healing In the followed series this condition was fulfilled, as the age distribution at follow up was known In the three series not followed, however the age distribution at a given time after primary healing may be determined on the basis of knowing the ages and the calendar year when the patients were started on treatment This is clearly apparent from Diagram 27 setting out the *traction* series The age distribution in this series can be found for any calendar year after 1963 (As already mentioned the normal mortality does not essentially alter the *age distribution* as the age dispersion *is relatively slight)*

Similar diagrams can be set up for the *bed rest* and *wheelchair* series

Incidentally the same method is applicable to Helbo's followed series in which patient age and calendar year at institution of treatment are known The development of osteoarthritis has been calculated on this basis – of course with practically *the same result* as when based upon age distribution at follow-up Thus if Ruelle' study had been known *it would have been possible already at primary healing in the 20 s to predict the development of osteoarthritis in the series so that follow-up more than 25*

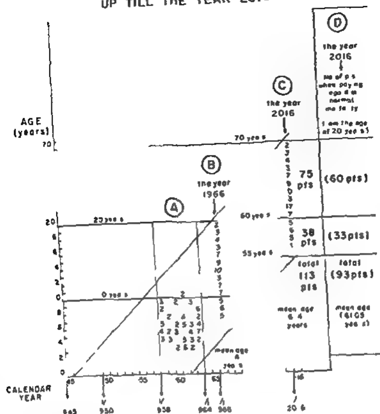

Diagram 27 Age development in the traction series up till the year 2016

A No of pts age year at admission
B C Age distribution in the Tr series in 1966 and in 2016

On the diagram within the two diagonal lines no regard is paid to normal mortality
Normal mortality (Stat Årbog 1968) reduces the number of patients from 113 in 1966 to 109 in 1996 but the age distribution and thereby the osteoarthritis rate is practically unaltered (1966 mortality not included osteoarthritis rate 8 4 % included about 8 4 %) Up to the year 2016 the number of patients is reduced to 93 but the calculated osteoarthritis rate is reduced only from 29 5 to 29 4 % (little age dispersion)

D This special column gives the age distribution and the mean age in 2016 paying regard to normal mortality since the age of about 20 (1976)

years later would have confirmed what had been predicted

In the three more recent series the maximum possible osteoarthritis rate may be determined with far more accuracy than in the followed series as the size of the threatened groups "PATH sph + "NON sph has been established by direct measurements (The percentages indicating the maximum possible rate of osteoarthritis will probably never come quite true unless some patients of the "NORM sph" group also develop osteoarthritis — which is of course not out of the question For further details concerning the "max possible" rate of osteoarthritis cf *Appendix, Comment 5*

In the followed series figures from Ruelle's total material (I + II) were used for calculating the expected rates of osteoarthritis In the three more recent series treated far more energetically the joint

Table 18 Development of clinical osteoarthritis presented for treatment in the Wh BR and Tr series as referred calculated using figures from Ruelle s group II c

% = % of osteoarthritis in survivors at the mean ages stated

The maximally possible osteoarthritis rate was fixed at 53 % in the Wh series 54 % in the BR series and 35 % in the Tr series

Mean age	Expected rate of clinical osteoarthritis					
	Wh series (as referred)		BR series (as referred)		Tr series (as referred)	
(years)	%	Calendar year	%	Calendar year	%	Calendar year
71	51	2026	53	2019	34	2026
61	45	2018	46	2009	28	2016
51	30	2006	32	1999	20	2006
41	13	1996	14	1989	8	1996
36	6	1991	4	1984	4	1991
26	1 3	1981	0 7	1974	0 6	1981

deformities left by the disease are probably far less pronounced than in the poorly treated, followed series Therefore, in calculating the *future* development of osteoarthritis in the wheelchair, bed rest, and traction series, the author used figures from *Ruelle's mildest group* of osteoarthritis (II c), viz those following upon acetabular dysplasia (120 patients) instead of from his total material Possibly, the joint deformities in Ruelle's group II c were somewhat milder than in our three series Using the figures from Ruelle's total material, we get somewhat higher osteoarthritis rates But the difference is not great Only, the figures are shifted roughly 5 years downward in age – i e the osteoarthritis develops 5 years earlier – but otherwise according to the same pattern as when using the figures from Ruelle's group II c (Diagram 23)

Table 18 gives the result of the calculations based upon the values from Ruelle's group II c

The expected rates of osteoarthritis at a mean age of 40 are low 8–14 % Between 40 and 50 the percentages double, and between 50 and 60 they rise by 50 % After the age of 60 the increase is slight

(The osteoarthritis rate may also be calculated in relation to the patients' 40th, 50th, and 60th *birthday* instead of the *mean age* of 40, 50, and 60 in the series This shows trebling of the osteoarthritis rate between the 40th and 50th birthday, as by this method we avoid the masking of the development of osteoarthritis caused by the use of the mean age The fact is that the osteoarthritis rates in the older and younger cases of the series alter less in the course of this decade than in the group around the mean age)

Of course the concrete figures in the table are fairly uncertain, but the *relations* between the results obtained in the three series and the pattern of the development through the years are probably correct

Table 18 shows the clinical long term prognosis in the three *series as referred*, calculated by the aid of Ruelle's values on the basis of the joint deformities present at primary healing

On the other hand, it does not afford reliable information about the *relative* efficacy of the three therapeutic methods, which is masked by the different severity of the series at referral

It is possible to throw light upon this aspect only by analysing the radiological and the consequent clinical results of the three methods in uniform parts of the three series – which affords small groups of patients – or in one series composed either as the *wheelchair series* the *bed rest* series or the traction series

In the radiological sections the author

arrived at the result that the latter method was more reliable *Therefore, the calculated* radiological results of the three therapeutic methods in *one* series of *the same* composition *as the wheelchair series* – or more correctly in three identical series thus composed – were used for determining the *efficacy of* the three therapeutic methods with a view to late clinical results The result *may* be seen from Table 19

In this table the development of osteoarthritis is *naturally* according to the same pattern as in Table 18 The order of magnitude of the figures has also not *changed but the picture of* the relative efficacy of the three therapeutic methods is more distinct not masked by the difference *in severity* between the three treated series

It is apparent that in this table the rate of osteoarthritis after *bed rest treatment* and *traction treatment* is lower in relation to that after *wheelchair treatment* than it was in Table 18 – after traction treatment only half that after wheelchair treatment

This seems a striking difference – but if the results are expressed in the percentage of cases *without* osteoarthritis it is not quite so outstanding At the mean age of 41 years 87 % are without osteoarthritis after wheelchair treatment and 94 % after traction a fairly unimportant *difference* At this mean age *all* three forms of treatment have given good results The relation between the few poor results is *not of* major practical importance

The *difference between* the percentage of cases *without* osteoarthritis (after the three methods) does not really manifest itself until the *mean* age of 51 years 70 %, 74 %, and 86 % after wheelchair, bed rest, and traction respectively Thus, after treatment by *traction* there are 23 % more cases without osteoarthritis than after treatment in wheelchair and at the mean age of 61 years 44 % more All this is *clearly* evident from Diagram 28 which *affords* a good survey of the expected late clinical results of the *three methods of treatment*

Using the *figures* from Ruelle's *total* material (I + II) gives a somewhat lower percentage of cases without osteoarthritis at the ages of *51* and *61*, as the osteoarthritis develops 5 years earlier

However, the use of Ruelle's mild group (II c) probably *affords the* more correct results

Then, Table 19 and Diagram 28 *afford the final answer* to the object of this study To establish the late clinical result of the three methods of treatment, when applied under uniform conditions

The *course of the study* which led to this result was First a description of the radio-

Table 19 Calculated development of clinical osteoarthritis presented for treatment in a series composed like the Wh series treated by Wh or BR or Tr

% = % of osteoarthritis in survivors at the mean ages stated

In the calculation figures from Ruelle's group II c were used

Table 18. Development of clinical osteoarthritis presented for treatment in the Wh, BR, and Tr series as referred, calculated using figures from Ruelle's group II c

% = % of osteoarthritis in survivors at the mean ages stated

The maximally possible osteoarthritis rate was fixed at 53 % in the Wh series, 54 % in the BR series, and 35 % in the Tr series

Mean age	Expected rate of clinical osteoarthritis					
	Wh series (as referred)		BR series (as referred)		Tr series (as referred)	
(years)	%	Calendar year	%	Calendar year	%	Calendar year
71	51	2026	53	2019	34	2026
61	45	2018	46	2009	[illegible]	2016
51	30	2006	32	1999	20	2006
41	13	1996	14	1989	8	1996
36	6	1991	4	1984	4	1991
26	1 3	1981	0 7	1974	0 6	1981

deformities left by the disease are probably far less pronounced than in the poorly treated followed series. Therefore, in calculating the *future* development of osteoarthritis in the wheelchair, bed rest, and traction series, the author used figures from Ruelle's *mildest group* of osteoarthritis (II c), viz. those following upon acetabular dysplasia (120 patients) instead of from his total material. Possibly, the joint deformities in Ruelle's group II c were somewhat milder than in our three series. Using the figures from Ruelle's total material, we get somewhat higher osteoarthritis rates. But the difference is not great. Only, the figures are shifted roughly 5 years downward in age, i.e. the osteoarthritis develops 5 years earlier, but otherwise according to the same pattern as when using the figures from Ruelle's group II c (Diagram 23).

Table 18 gives the result of the calculations based upon the values from Ruelle's group II c.

The expected rates of osteoarthritis at a mean age of 40 are low: 8–14 %. Between 40 and 50 the percentages double, and between 50 and 60 they rise by 50 %. After the age of 60 the increase is slight.

(The osteoarthritis rate may also be calculated in relation to the patients' 40th, 50th, and 60th *birthday* instead of the *mean age* of 40, 50, and 60 in the series. This shows trebling of the osteoarthritis rate between the 40th and 50th birthday, as by this method we avoid the masking of the development of osteoarthritis caused by the use of the mean age. The fact is that the osteoarthritis rates in the older and younger cases of the series alter less in the course of this decade than in the group around the mean age.)

Of course the concrete figures in the table are fairly uncertain, but the *relations* between the results obtained in the three series and the pattern of the development through the years are probably correct.

Table 18 shows the clinical long term prognosis in the three *series as referred* calculated by the aid of Ruelle's values on the basis of the joint deformities present at primary healing.

On the other hand, it does not afford reliable information about the *relative* efficacy of the three therapeutic methods which is masked by the different severity of the series at referral.

It is possible to throw light upon this aspect only by analysing the radiological and the consequent clinical results of the three methods in uniform parts of the three series – which affords small groups of patients – or in one series composed either as the wheelchair series, the bed rest series or the traction series.

In the radiological sections the author

arrived at the result that the latter method was more reliable Therefore, the calculated radiological results of the three therapeutic methods in *one* series of *the same composition as the wheelchair series* – or more correctly in three identical series thus composed – were used for determining the efficacy of the three therapeutic methods with a view to late clinical results The result may be seen from Table 19

In this table the development of osteoarthritis is naturally according to the same pattern as in Table 18 The order of magnitude of the figures has also not changed but the picture of the relative efficacy of the three therapeutic methods is *more distinct, not masked by the difference in severity between the three treated series*

It is apparent that in this table the rate of osteoarthritis after *bed rest treatment* and *traction treatment* is lower in relation to that after *wheelchair treatment* than it was in Table 18 after traction treatment only half that after wheelchair treatment

This seems a striking difference but if the results are expressed in the percentage of cases *without* osteoarthritis it is not quite so outstanding *At the mean age of* 41 years 87 % are without osteoarthritis after wheelchair treatment and 94 % after traction, a fairly unimportant difference *At this mean* age *all* three forms of treatment have given good results The relation between the few *poor* results is not of major practical importance

The difference between the percentage of cases *without osteoarthritis* (after the three methods) does not really manifest itself until *the mean* age of 51 years 70 %, 74 %, and 86 % after wheelchair, bed rest, and traction respectively Thus, after treatment by *traction there are* 23 % more cases without osteoarthritis than after treatment in wheelchair and at the mean age of 61 years 44 % more All this is *clearly evident* from Diagram 28 which affords a good survey of the expected late clinical results of the three methods of treatment

Using the figures from Ruelle's total material (I + II) gives a *somewhat lower* percentage of cases without osteoarthritis at the ages of 51 and 61, as the osteoarthritis *develops 5 years earlier*

However, the use of Ruelle's mild group (II c) probably affords the more correct results

Then, Table 19 and Diagram 28 afford *the final answer to the object of this study* To establish the late clinical result of the three methods of treatment, *when applied under uniform conditions*

The *course of the study* which led to this result was First a description of the *radio-*

deformities left by the disease are probably far less pronounced than in the poorly treated, followed series Therefore, in calculating the *future* development of osteoarthritis in the wheelchair, bed rest, and traction series, the author used figures from *Ruelle's mildest group* of osteoarthritis (II c), viz those following upon acetabular dysplasia (120 patients) instead of from his total material Possibly, the joint deformities in Ruelle's group II c were somewhat milder than in our three series Using the figures from Ruelle's total material, we get somewhat higher osteoarthritis rates But the difference is not great Only, the figures are shifted roughly 5 years downward in age – i e the osteoarthritis develops 5 years earlier – but otherwise according to the same pattern as when using the figures from Ruelle's group II c (Diagram 23)

Table 18 gives the result of the calculations based upon the values from Ruelle's group II c

The expected rates of osteoarthritis at a mean age of 40 are low 8–14 % Between 40 and 50 the percentages double, and between 50 and 60 they rise by 50 % After the age of 60 the increase is slight

(The osteoarthritis rate may also be calculated in relation to the patients' 40th, 50th, and 60th *birthday* instead of the *mean age* of 40, 50, and 60 in the series This shows trebling of the osteoarthritis rate between the 40th and 50th birthday, as by this method we avoid the masking of the development of osteoarthritis caused by the use of the mean age The fact is that the osteoarthritis rates in the older and younger cases of the series alter less in the course of this decade than in the group around the mean age)

Of course the concrete figures in the table are fairly uncertain, but the *relations* between the results obtained in the three series and the pattern of the development through the years are probably correct

Table 18 shows the clinical long-term prognosis in the three *series as referred*, calculated by the aid of Ruelle's values on the basis of the joint deformities present at primary healing

On the other hand, it does not afford reliable information about the *relative* efficacy of the three therapeutic methods, which is masked by the different severity of the series at referral

It is possible to throw light upon this aspect only by analysing the radiological and the consequent clinical results of the three methods in uniform parts of the three series – which affords small groups of patients – or in one series composed either as the wheelchair series, the bed rest series, or the traction series

In the radiological sections the author

exact figures (31 %, 47 %, etc) This numerical accuracy does not reflect the real uncertainty – which is appreciable

The sources of error are numerous, and *it is difficult* to assess their role

The calculations are based upon different figures *Measurements* on X ray films of varying accuracy, *figures* from reports in the literature, *often of* regrettable brevity and questionable relevance

Lastly, the correctness of the calculation depends entirely upon whether these uncertain figures are interpreted and used in the right way

En route to these final tables – and others similar to it in the clinical section – there are in short so many factors of *uncertainty* and so many *pitfalls* that it may be asked whether the efforts were worth while

To this *scepticism it may* be rejoined that at present at *least there* is no other possibility of *elucidating these problems*

Moreover, the uncertainty is hardly *so* great that the results can be dismissed as being of no major interest

True, the concrete figures should no doubt be regarded with a great deal of reserve However, the *relations* between the tabulated figures, vertical as well as horizontal, are based upon so much consistent evidence, obtained by different methods of measurement and calculation, that in broad features they will probably prove to correspond to the actual findings at the time when sufficiently late follow up studies can be *performed* – i e when the mean age is at least 60 years

In the case of our three series this will not be until the years 2009–2016

POSTSCRIPT 1974 TO CLINICAL SECTION

Attempt at Checking the Calculated Late Development of Osteoarthritis in HELBO's *Series*

A Follow-up After a Minimum of 50 Years

After completing the work described above the present author in collaboration with Mose et al – conducted a follow up examination in 1974 of those who could be traced of Helbo's *patients* who had attended follow up already in 1950 Regrettably it was possible to trace only 25 of the 36 who are presumed to be still alive From a statistical point of view therefore the results are very uncertain

In 1974 all 25 patients had been followed for *more than 50 years* – mean *follow up period* 57 years Their mean age was 65 approximately the same mean age *and age* distribution that might be expected *if all survivors had been traced*

A detailed account of the total result will be published later by Mose et al Here *follows* merely a brief report of that part of the results which bears relation to the problems of the present study

It must be pointed out first that what characterizes Ruelle's patients is that sooner or later all *applied for institutional treatment* of their arthritic symptoms No mention *is made of* any other characteristic of their osteoarthritis

Therefore, if the osteoarthritis rates *calculated* on the basis of Ruelle's figures are *to be compared* with those actually found, *they have to be* compared with the percentage of patients found who had applied for *treatment* of their osteoarthritis (Appendix *Comment 5*)

However, Ruelle's figures comprise also a small *number of patients* who had *not yet* applied *for treatment* at the ages stated – though decreasing as time went by (Appen-

CALCULATED DEVELOPMENT OF OSTEOARTHRITIS IN THE Wh SERIES AT 3 DIFFERENT METHODS OF TREATMENT

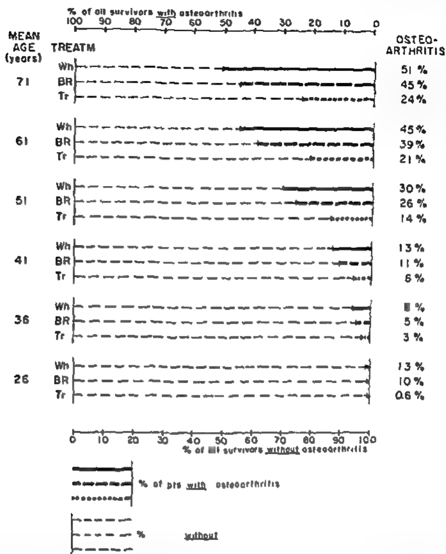

Diagram 28 Expected (calculated) clinical osteoarthritis (pts applying for treatm.) in a series composed like the Wh series (with regard to age and stage at institution of treatment) after 3 different methods of treatment (Wh BR and Tr)

% of survivors calculated by using figures from Ruelle's group II c

The series are arranged according to – → + osteoarthritis from L to R

logical results obtained by the three methods – paying particular regard to the fact that the methods had been applied to series of different severity

Thereafter, a review of the available *follow-up reports of LCPD series* This afforded a picture of the actual development of radiological and clinical osteoarthritis in more or less effectively treated series up to the mean age of approx 40

Finally, studies of special *series of osteoarthritis* (int al Ruelle's) supplied information as to how symptoms of secondary osteoarthritis developed up to an advanced age after different degrees of articular deformity

By a combination of these three groups of data – *radiological and clinical* the author arrived at the figures set out in Tables 18 and 19

The figures in these tables were obtained by calculation – and they are stated in

is demanded *I therefore* ventured to use Ruelle's figures for calculating the size of the group of patients who had applied for treatment up to an advanced age.

According to Table 16, this group would be expected to make up 85 % of all survivors in 1970, 20 years after the follow up examination, and in 1974 90 % If the relation of this calculated percentage to the percentage of patients who had applied for treatment actually found was the same in 1974 and in 1950, 75 % of the survivors would be expected to have applied for treatment of osteoarthritis in 1974

But as already mentioned, it must be anticipated that the older the patients get, the higher a percentage of the calculated number – and incidentally of all patients with radiological osteoarthritis – will have applied for treatment of their symptoms In other words, it must be expected that the number of patients with osteoarthritis who had applied for treatment will approach the calculated rate with advancing age – and that in 1974 it ought to be somewhere between 75 % and 90 % of the surviving patients

The actual finding was 84 per cent

Thus the rate was 93 % of the calculated rate as compared with only 83 % in 1950

It may be added that the majority of the 84 % patients who had applied for treatment of osteoarthritis were also more or less disabled (76 % of the total patients)

Diagram 29 clearly sets out the relations between the calculated and found values – in *1950* and in *1974* (cf also the legend)

However the values listed in the diagram require a comment

All the percentages, *found* and *calculated* in 1974 *are maximum values*

Of the cases of *radiological* osteoarthritis found 2 or 3 must be said to be questionable even to experienced radiologists (Helbo's Cases 58, 112, and 119) They are included as radiological osteoarthritis, because the presence of *radiological osteoarthritis* cannot be excluded

The number of patients found with *clinical* osteoarthritis (21) is also at the upper limit

It is common to them all that at some time or other they had applied for *treatment of their symptoms* In other respects they fall into several groups

The largest group (12/21) had symptoms and signs of *osteoarthritis of the hip only* – and no complicating features All could indubitably be called cases of secondary osteoarthritis of the hip

But a smaller – but nevertheless a surprisingly large – group (9/21) had, in addition to symptoms and signs of osteoarthritis of the hip, also low-back pain, lumbago, stiffness of the back with limitation of movement, radiating pain in the legs, etc

Some had only backache *without* objective signs of vertebral disease – evidently *merely pain radiating from the hip disease* – but the majority had *radiological changes of the spine*, indicating that in fact the *back complaints originated from the spine* There might be merely static changes in the shape of the spine, scoliosis, lordosis, etc *or signs of actual diseases Spondylarthritis*, degeneration of intervertebral discs, spondylolisthesis, etc

In these cases the back complaints usually appeared later than – occasionally at the same time as – the symptoms of *osteoarthritis of the hip When also considering* the striking frequency of back complaints in the material, *this rendered it likely that* an essential *proportion of* the vertebral lesions had developed *secondarily* to the osteoarthritis of the hip, possibly to the primary LCPD

In cases where the back complaints were merely a *superstructure* on well-defined osteoarthritis symptoms *from the hip (5 patients), they could rightly be assigned to the group osteoarthritis of the hip* The back complaints – and the underlying vertebral lesions – were in fact *merely a further development* of pure "secondary osteoarthritis of the hip" Yet, it must be

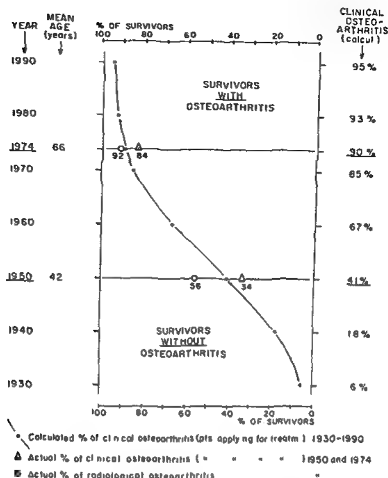

Diagram 29 Calculated *development of clinical osteoarthritis (pts applying for treatm) in Helbo s series (I–HE) performed by using figures from Ruelle s total material (I + II)*

% = % of survivors

The diagram also lists the osteoarthritis rates found at Helbo's follow up examination in 1950 and at the follow-up examination in 1974

It will be seen that the clinical osteoarthritis rates calculated for 1950 and 1974 (pts applying for treatm), 41 % and 90 % are – as might be expected – somewhat higher than those found (34 % and 84 %) because the calculated rates comprise a small number of patients who have not yet applied for treatment

Comment Diagram 29 is not quite correct The curve was traced on the presupposition that the follow up examination in 1974 comprised all survivors from Helbo s 1950 follow up examination but it comprises only part of them (25/36 pts) However if the calculation for 1974 is performed with the correct mean age and age distribution the result will be only a trifle lower than the figures on the curve (88 5 %/90 %)

Thus, it seems permissible to trace the curve together with the results of both follow up examinations

This renders the diagram more instructive

dix Comment 5) Thus, osteoarthritis rates calculated on the basis of Ruelle's figures must be expected to be somewhat higher than the percentages of patients who had applied for treatment found at follow-up

From Table 14 it is apparent that at follow-up in 1950–1951 Helbo found signs of *radiological* osteoarthritis in 56 % of the patients and that 34 % had applied for treatment because of its symptoms

Calculation using Ruelle's figures resulted in 41 % who had applied for treatment of osteoarthritis – indeed, as expected, a somewhat higher rate than that actually found

This was an agreement as close as could

be said to constitute a risk to LCPD patients

Let it be added that these cases of mild, but typical LCPD had healed with *"spherical heads"* In other words, they afford examples that healing with spherical heads *is no guarantee* against the development of radiological osteoarthritis of the hip and late hip-back symptoms

Yet another case (HE No 85) had healed with a spherical head In this case there were no radiological signs of osteoarthritis, and the patient was symptom free

From this review it is apparent that the great majority of these cases of secondary osteoarthritis of the hip, hip back symdrome and late symdromes in general may be collected under the designation secondary osteoarthritis of the hip in an *extended sense* as described above

The few cases – at an estimate two or three – in which there could be some doubt *were nevertheless* assigned to this group *This means of course* that the percentage of patients with clinical osteo arthritis *found* in 1974 and depicted in Diagram 29 must be regarded as a maximum percentage – just like that of patients with radiological osteoarthritis

The *calculated percentage of patients* with clinical osteoarthritis is also a *maximum value*

All calculations are based upon the radiologically estimated "maximum possible percentage" of osteoarthritis in the material ≈ 95 % i e the radiological groups "NON sph " *and* "PATH sph " combined It was found however that *this percentage* had to be reduced at least somewhat – probably to about 90 % as 4 6 per cent of the *potential* cases of osteoarthritis will die before they develop osteoarthritis In *addition* a few of the numerous potential osteoarthritics will *indubitably* not develop the expected osteoarthritis even though they live to a ripe old age When *considering* the relation of the *calculated* percentage to that *found* at Helbo's follow-up study *in 1950 – whose correctness* we are unable to check and therefore must accept – such further reduction cannot, however, exceed about 5 % (to approx 85 %) – at least not if figures from Ruelle's total material (RU I + II) are to be used in the calculation (If the reduction is to be greater, figures from one of Ruelle's smaller groups have to be used in the calculations (e g RU I))

It must be pointed out that *a possible* reduction *in the final maximum osteoarthritis rate cannot* alter the fact that all patients in 95 % of the material – i e in the patient groups "NON-sph " and "PATH sph " – are at risk, since the reduced, final percentage of cases of osteoarthritis will spread over *95 %* of the material

However, it is extremely difficult to fix the correct magnitude of such a reduction Therefore, *the more accurately defined* 95 % *will be maintained as a basis for the* calculations

This makes the rate of clinical osteoarthritis in Helbo's material *calculated* for 1974 also a *maximum percentage* – like the radiological and clinical rates of osteoarthritis actually *found*

Of course, the *calculated* and the *two found* maximum values may be reduced (by *approx* 8–12 % for all three rates) to values which are perhaps *more realistic*, but the reduced values will presumably *prove* even more uncertain than the maximum ones

And this does not essentially alter the relation between the rates

After these comments the result of the follow-up *study may* be briefly worded as follows

92 % of the patients exhibited *definite* – or possible – signs of radiological osteoarthritis

84 % had applied for treatment of secondary sequelae to LCPD – as a rule secondary *osteoarthritis* of the hip A number of

conceded that in these cases the term osteoarthritis of the hip embraces a more comprehensive syndrome than indicated by the name A more apt term might be *"secondary hip-back syndrome"*, perhaps only "late secondary syndrome" It is indeed by no means certain that the late sequelae to LCPD are restricted to these two skeletal sites

In a small number of patients (4) the radiological signs of osteoarthritis in the hip were not marked, but indubitable, and the hip symptoms were so mild that the *back complaints were predominant* In such cases it was more doubtful whether the term osteoarthritis of the hip was justified

However, in a couple of these patients the back complaints were evidently due essentially to static abnormality of the spine, caused by the *primary hip deformity* following upon LCPD However, the temporal occurrence – and exacerbation – of the back symptoms does not seem unrelated to the development of the mild *osteoarthritis* of the hip *Therefore, these hip back syndromes might also be interpreted as secondary osteoarthritis of the hip* in an extended sense At least they were secondary to LCPD

In the *remaining two patients* with mild symptoms and signs of osteoarthritis, the relation of the vertebral disease to that of the hip – the primary LCPD or the osteoarthritis – was more questionable There might be a chance coincidence of hip and back disease, but a relation to the hip disease could not be excluded in either case

Experience has shown that LCPD is not merely a local hip disease, but is associated with a generally altered state of the entire skeleton – manifesting itself int al in delayed development of the ossification centres in the carpus, reduced longitudinal growth, and the not uncommon occurrence of "aseptic necroses" in other epiphyses – "multiple aseptic epiphyseal necroses"

Apart from this, LCPD, or LCPD like radiological changes are not uncommonly encountered as part of certain, familial "enchondral dysostoses" (Mau 1958), in particular dysplasia epiphysialis multiplex and Morquio's symdrome (Rubin, Fairbank) *In mild and early cases of these two syndromes the differential diagnosis against pure LCPD may even be difficult* (Fairbank 1951)

Morquio's syndrome usually involves considerable deformities of the vertebrae – dysplasia epiphysialis multiplex more rarely The question now arises whether some of our combined hip-back syndromes might be examples of such combined *skeletal diseases* on a constitutional basis, especially the cases in which the back disease was not likely to be secondary to the hip disease

In *one of these cases* (Helbo's Case 1) the hip disease was combined with a congenital spinal defect and an atypical disease of the central nervous system (CNS) "presumably" disseminated sclerosis
With regard to the latter complication, it is enlightening that five familial cases of such combined disease of the hip, pelvis, spine, and CNS have been reported by Jequier and Streiff (1947) In their opinion the disease of the hip represented the sequelae to LCPD, the diseases of the CNS had features of congenital spastic paraplegia as well as of disseminated sclerosis
The other case (Helbo's Case 107) is spondylolisthesis of the type which is familial (Newmann 1963) Newmann feels that the cause of this type is most probably stress fracture arising in constitutionally weakened bony tissue (+ ligaments)
In both cases the symptoms were of late onset

These two cases might be interpreted as combined hip back diseases on a constitutional basis – and the possibility that such cases *may* develop in a LCPD material *must*

CONCLUDING REMARKS

1 Out patient and In patient Treatment

The main result of the present study is that in patient treatment with traction affords better results than bed rest in hospital without traction and out patient treatment in wheelchair This is apparent from the X ray films already at primary healing – but does not manifest itself clinically until an age of almost 50

Thus the choice between in patient treatment with and without traction is not difficult

It is a different matter when choosing between in patient treatment with traction and out patient treatment in wheelchair During the 1950's and 1960's there have been constant paediatric warnings against treating children in hospital It is claimed that a stay in hospital is a greater strain and psychlologically far more harmful than treatment carried out at home The most convinced adherents of these views are even prepared to accept an essentially poorer somatic result if only the treatment takes place at home

Therefore before choosing between in-patient and out patient treatment, one must make up one's mind about these still widely held views on the harmful effect of hospital treatment upon children

Are they based on realities?

To me it is doubtful

At the Seaside Hospital, Refsnæs, about 500 children with LCPD have been treated Of them I have seen 300–400

Children with LCPD are put into 4–8 bed wards, and all are so to speak "in the same boat", where nobody can feel "odd man out" in the environment They are surrounded by an experienced and large staff of doctors, nurses, nurses' aides, occupational therapists, and teachers to look after their correct treatment, entertainment, occupation, and instruction

Nothing amuses children more than being with other children in the same situation and of the same age Throughout the day, this companionship – indoors and out of doors – is full of diversions and fun The result has been largely a collection of happy and well adapted children with whom it has been a daily encouragement to associate

I have followed all the children until they were 16–18 years of age, and neither their parents nor I have found that they differed in any way mentally from a corresponding group of children and adolescents who have never been ill

On this background I try to visualize out patient treatment with crutches or wheelchair at home – possibly in a flat – among healthy sisters, brothers, and mates under the responsibility of anxious parents I must confess that I have some difficulty

these elderly *patients*, however, had developed a hip-back syndrome, in a few of them even with predominance of the back complaints

Nevertheless, all could be assigned to the group with secondary osteoarthritis of the hip on the grounds stated above

The main object of the follow-up study was to check the calculated percentage of patients who had applied for treatment of secondary osteoarthritis up to 1974

According to the calculation 90 % of the patients would be expected to belong to this group At follow-up the rate was found to be 84 %

As it had been anticipated that the calculated rate was somewhat higher than that found, it must be concluded that the pre-calculated percentage afforded reasonably good guidance concerning the percentage that would be found in 1974

Diagram 29 then affords a perspicuous survey of the agreement between the calculated and found rates of osteoarthritis in Helbo's material at the follow-up studies in 1950 and in 1974

Despite all uncertainty, such an agreement ascertained at repeated late follow up studies of Helbo's patients – most recently with a follow-up period exceeding 50 years – must strengthen confidence in the calculations performed to predict the development of osteoarthritis in the three more recent series treated *by wheelchair, bed rest without traction*, and *bed rest with traction*

However, as already mentioned, the correctness of these predictions cannot be checked until at follow-up of the patients after the year of 2000

CONCLUDING REMARKS

1 Out patient and In patient Treatment

The main result of the present study is that in patient treatment with traction affords better results than bed rest in hospital without traction and out patient treatment in wheelchair This is apparent from the X ray films already at primary healing – but does not manifest itself clinically until an age of almost 50

Thus, the choice between in patient treatment with and without traction is not difficult

It is a different matter when choosing between in patient treatment with traction and out patient treatment in wheelchair During the 1950s and 1960's there have been constant paediatric warnings against treating children in hospital It is claimed that a stay in hospital is a greater strain and psychlologically far more harmful than treatment carried out at home The most convinced adherents of these views are even prepared to accept an essentially poorer somatic result if only the treatment takes place at home

Therefore before choosing between in patient and out patient treatment, one must make up one's mind about these still widely held views on the harmful effect of hospital treatment upon children

Are they based on realities?

To me it is doubtful

At the Seaside Hospital, Refsnæs, about 500 children with LCPD have been treated Of them I have seen 300–400

Children with LCPD are put into 4–8 bed wards, and all are so to speak "in the same boat", where nobody can feel "odd man out" in the environment They are surrounded by an experienced and large staff of doctors, nurses, nurses' aides, occupational therapists, and teachers to look after their correct treatment, entertainment, occupation, and instruction

Nothing amuses children more than being with other children in the same situation and of the same age Throughout the day, this companionship – indoors and out of doors – is full of diversions and fun The result has been largely a collection of happy and well adapted children with whom it has been a daily encouragement to associate

I have followed all the children until they were 16–18 years of age, and neither their parents nor I have found that they differed in any way mentally from a corresponding group of children and adolescents who have never been ill

On this background I try to visualize out patient treatment with crutches or wheelchair at home – possibly in a flat – among healthy sisters, brothers, and mates under the responsibility of anxious parents I must confess that I have some difficulty

in convincing myself that treatment at home is on the whole less of a strain on the children than treatment in hospital

On the basis of my, somewhat one-sided, experience, I can only say with certainty The majority of the children adjust surprisingly well to hospital life This may seem surprising, but it remains a fact The explanation is probably that children have an amazing ability to put up with and remain unaffected even by the most peculiar circumstances

To me, therefore, it is difficult to perceive the harmful effect of hospital treatment upon children – on the understanding that it takes place in a well-suited institution As the somatic results of traction in hospital are – according to what has been stated above – definitely superior to those of out-patient treatment in wheelchair, I find no difficulty in concluding that

Children with LCPD should, as far as possible, be treated by traction in hospital

But of course it must be admitted that this is not always possible

In the first place a small number of children cannot put up with treatment in hospital and a small number of parents cannot do without their children at home Under such circumstances it should naturally be endeavoured to carry out home treatment as effectively as possible

In the second place, a suited institution is not at disposal everywhere This is probably the most common motivation for choosing out-patient treatment

From my 1966 publication the present study, and Jorgen Lauritzen's it is apparent that out-patient treatment in wheelchair is considerably more effective than out-patient treatment with a Thomas caliper It has the great advantage among others that it permits non-weightbearing in *both* hips Therefore bilateral cases can also be treated – and in unilateral cases the very regrettable secondary development of LCPD in the "good" hip is avoided

I doubt that a more effective out-patient treatment is available

2 Radiological and Clinical Evaluation by Two Examiners

The radiological evaluations in the present study are of little value, if the measurements on which they are based cannot be reproduced with approximately the same result by others without a knowledge of J M 's measuring results

Therefore, as already mentioned, the X-ray films of all patients in the three series were measured not only by J M , but also independently, by Lauritzen (LAU), who reported his results in 1975 (Diss)

A total of about 4000 measurements were performed by both examiners – plus reading of 112 films showing non-spherical heads – for which the only "measurement" needed was ascertaining the absence of a spherical shape by means of Mose's plate

In a large number of cases the examiners measured on the same film, but owing to the shift in the time of measurement in several cases, on different films of the same patient I even did an extra series of measurements in the traction series to adapt the observation periods to LAU's

Therefore, direct comparison of the measurements for each individual patient is of less interest – but can be done by comparing J M 's and LAU's patient lists The patients of the traction and bed rest series have identical numbers in both publications A list of the corresponding numbers in the wheelchair series may be seen in the Appendix before the patient lists

What is of interest is the comparison of the two sets of evaluation *results* obtained by the use of the independent measurements by the two examiners – in particular to ascertain whether agreement exists between the results affording the most reliable picture of the relative efficacy of the three methods of treatment The results in the same series or in 3 identical series

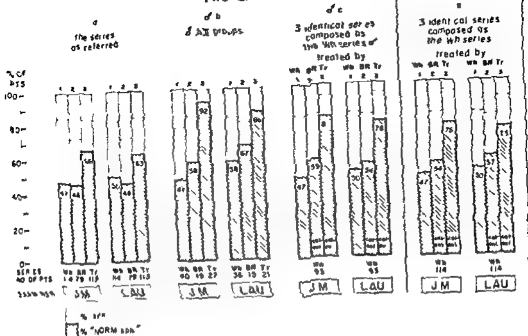

Diagram 30 Radiological results of treating the listed series and groups of patients by Wh BR and Tr based upon measurements on X ray films performed by 2 examiners independently of each other

The columns show the results of treating

				JM^{1})	LAU^{2})
a	1	*the Wh series as referred by Wh*	(SPH	85 %	82 %)
	2	*the BR series as referred by BR*	(	73 %	72 %)
	3	*the Tr series as referred by Tr*	(	84 %	84 %)
♂b	1	*the ♂A II group of the Wh series by Wh*	(SPH	77 %	83 %)
	2	*the ♂A II group of the BR series by BR*	(	84 %	80 %)
	3	*the ♂A II group of the Tr series by Tr*	(	100 %	100 %)
♂c	1	*the ♂ of the Wh series as referred by Wh*	("SPH "	82 %	83 %)
	2	*the ♂ of the Wh series as referred by BR (cal.)*	(	83 %	82 %)
	3	*the ♂ of the Wh series as referred by Tr (cal.)*	(	93 %	94 %)
c	1	*the Wh series as referred by Wh*	("SPH	85 %	82 %)
	2	*the Wh series as referred by BR (cal.)*	(	82 %	80 %)
	3	*the Wh series as referred by Tr (cal.)*	(	91 %	90 %)

A total survey of the radiological results (JM) is given in the Appendix Table 27

The 3 groups of patients designated ♂b are the prognostically most uniform ones that can be singled out of the series but the results in group c are probably of most practical interest

[1]) *JM % calculated using JM s measurements by JM* [2]) *LAU % calculated using LAU s measurements by JM*

(Abbreviations and symbols p 12)

which may be calculated from Lauritzen' as well as from my figures

As a main example Diagram 30 (c) shows the results of the 3 therapeutic methods in a series composed like the wheelchair series, as these results have some practical perspective (Of course, series composed like the traction or bed rest series would

in convincing myself that treatment at home is on the whole less of a strain on the children than treatment in hospital.

On the basis of my, somewhat one-sided, experience, I can only say with certainty The majority of the children adjust surprisingly well to hospital life. This may seem surprising, but it remains a fact The explanation is probably that children have an amazing ability to put up with and remain unaffected even by the most peculiar circumstances

To me, therefore, it is difficult to perceive the harmful effect of hospital treatment upon children – on the understanding that it takes place in a well-suited institution. As the somatic results of traction in hospital are – according to what has been stated above – definitely superior to those of out-patient treatment in wheelchair, I find no difficulty in concluding that

Children with LCPD should, as far as possible, be treated by traction in hospital

But of course it must be admitted that this is not always possible

In the first place a small number of children cannot put up with treatment in hospital and a small number of parents cannot do without their children at home Under such circumstances it should naturally be endeavoured to carry out home treatment as effectively as possible

In the second place, a suited institution is not at disposal everywhere This is probably the most common motivation for choosing out-patient treatment

From my 1966 publication, the present study, and Jørgen Lauritzen's it is apparent that out-patient treatment in wheelchair is considerably more effective than out-patient treatment with a Thomas caliper It has the great advantage, among others, that it permits non-weightbearing in *both* hips Therefore, bilateral cases can also be treated – and in unilateral cases the very regrettable secondary development of LCPD in the "good" hip is avoided

I doubt that a more effective out-patient treatment is available.

2. Radiological and Clinical Evaluation by Two Examiners

The radiological evaluations in the present study are of little value, if the measurements on which they are based cannot be reproduced with approximately the same result by others without a knowledge of J M 's measuring results

Therefore, as already mentioned, the X-ray films of all patients in the three series were measured not only by J M , but also, independently, by Lauritzen (LAU), who reported his results in 1975 (Diss).

A total of about 4000 measurements were performed by both examiners – plus reading of 112 films showing non-spherical heads – for which the only "measurement" needed was ascertaining the absence of a spherical shape by means of Mose's plate

In a large number of cases the examiners measured on the same film, but owing to the shift in the time of measurement in several cases, on different films of the same patient I even did an extra series of measurements in the traction series to adapt the observation periods to LAU's

Therefore, direct comparison of the measurements for each individual patient is of less interest – but can be done by comparing J M 's and LAU's patient lists The patients of the traction and bed rest series have identical numbers in both publications A list of the corresponding numbers in the wheelchair series may be seen in the Appendix before the patient lists

What is of interest is the comparison of the two sets of evaluation *results* obtained by the use of the independent measurements by the two examiners – in particular to ascertain whether agreement exists between the results affording the most reliable picture of the relative efficacy of the three methods of treatment The results in the same series or in 3 identical series

scribed the efficacy of his treatment with that of *wheelchair*, bed rest, and traction treatment as described in the present study

Such a possibility of comparison must facilitate the efforts at arriving at therapeutic methods affording an even *better* radiological result

Similar agreement between two examiners can be obtained also by means of simpler methods of evaluation, the "one-quotient methods" mentioned above

Diagram 31 is an example (cf also Appendix Comment 2)

But the *radiological* result is not the essential thing only a basis for the evaluation of the *final clinical result* which is decisive The agreement between LAU and J M comes to an end at least partially in predicting the clinical consequences of the radiological results i e in deciding which radiological group of patients will presumably not develop secondary osteoarthritis even at an advanced age and which groups are at risk

My investigations led to the conclusion that only patients in the radiological group called "NORM sph " (= LAU's "excellent") obtained a radiological result preventing in all essentials the development of secondary osteoarthritis LAU on the other hand feels that all patients of the "spherical" group (= J M 's "SPH") will remain free of osteoarthritis (LAU Thesis 1975 p 36)

LAU as well as J M have based their conclusions concerning the clinical implications of the radiological result mainly on the review of a number of reports in the literature on follow up of patients with a history of LCPD during childhood – but they have not arrived at the same result

In a detailed review of 19 reports on follow up studies (described in the present publication pp 39–52) on which I based my conclusion it was evident that several difficulties were involved in drawing a conclusion regarding the relation of the *primary radiological result* to *subsequent development of osteoarthritis* These difficulties have not quite manifested themselves in LAU's review of the literature used by him But of course they are present also in these reports, all the more so as they *are largely* the same as those reviewed by J M

First, the majority of the follow up studies on which LAU based his conclusion were carried out at too early an age – in the early or middle twenties As secondary osteoarthritis usually does not properly start until the forties, it is not surprising that LAU found osteoarthritis only in cases with the most severe deformities The latest follow up studies were in fact also too early – the mean age being only about 40

Secondly, "spherical" and "round" in the literature usually means "golf ball-shaped" or more correctly "3/4 *golf ball* shaped", i e exactly "NORM sph " – in LAU's terminology "excellent" – and certainly not "spherical" as defined by Mose and used by LAU himself – and J M – to characterize the cases in the "spherical" group – J M 's " SPH "

The group "spherical" ("SPH") in LAU's, J M 's, and Mose s sense is a *far more comprehensive* group than the "spherical" in the literature, comprising several appreciably deformed cases, cases with mushroom-shaped heads but with a circular outline as defined by Mose (cf Fig 1 a and b)

Therefore although the "spherical" group from the literature seems to avoid osteoarthritis LAU cannot draw the conclusion that *his* "spherical" group will avoid it As substantiated by the present author the conclusion that can be drawn from the literature is that only patients of the group "NORM sph " ("excellent") remain free of osteoarthritis

But *when* LAU applied *his* criterion – that all patients of the "spherical" group remain free *of osteoarthritis* – to evaluating the efficacy of the various therapeutic methods he arrived in fact at the same *main* conclusion (LAU Thesis 1975 pp

2 EXAMINERS
"I QUOTIENT ASSESSMENT" USING THE RADIUS QUOTIENT

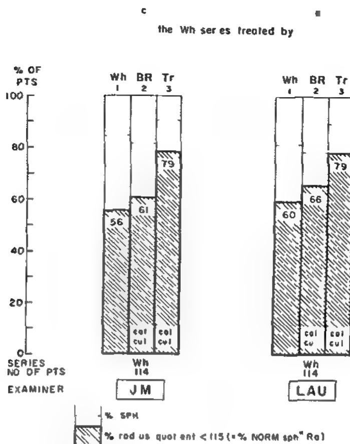

Diagram 31 Radiological results when treating the Wh series as referred by Wh BR or Tr (the results of BR and Tr calculated)

The assessment was exclusively by the aid of the radius quotient *(I quotient assessment) measured by 2* examiners *independently of each other*

Radiological result of treating

			JM[1])	LAU[2])
c	1 The Wh series as referred by Wh	(SPH	85 %	82 %)
	2 The Wh series as referred by BR	(	82 %	80 %)
	3 The Wh series as referred by Tr	(	91 %	90 %)

[1])*JM % calculated using JM s measurements by JM*

[2])*LAU % calculated using LAU s measurements by JM*

(% NORM sph Ra cf p 20 Other abbreviations and symbols on p 12)

have served just as well) As a supplement the two examiners' results in other series and groups of patients are shown (a d b d c) Particular interest perhaps attaches to the direct results in the three series as referred (a)

According to the diagrams the agreement between the two examiners' results in all series and groups of patients is in fact amazing In the main example (a) the percentages of "NORM sph " differ by at most 3 % and of SPH ' by at most 5 % (of all patients)

In other words two examiners working independently can perform the numerous measurements with such a degree of agreement that they arrive at practically the same evaluation of the efficacy of the three therapeutic methods

In consequence any clinician treating LCPD has a possibility of comparing by the use of the measuring methods de

Thus, LAU's optimistic evaluation of the *clinical sequelae in group* "SPH" leads to an underestimate of the difference between the efficacy of traction and wheelchair treatment – and thereby to recommendations for treatment differing from those in the present publication LAU states, for instance, in his thesis p 129, that it is relatively immaterial how the patients of the oldest and youngest age group are treated, the results of traction not being essentially superior to those of wheelchair treatment In only one, special group of patients in the middle age group does LAU feel that traction is a definite advantage

The use of J M 's criterion of a good result – % "NORM sph" – gives the results in the age/stage groups as shown in Diagram 4 (J M 's measurements) In all age/stage groups there is an appreciable difference in the results between wheel chair and traction treatment This difference is moreover, accentuated in the oldest and especially the youngest age group when using LAU's own measurements (Diagram 32)

The conclusion drawn from these results must be that as a general rule all age groups – also the oldest and youngest – should be treated by traction (Of course, individual contra indications may exist)

In brief The two examiners LAU and J M measured the X ray films with identical results – but evaluated the clinical consequences of the radiological results differently

However, it must be emphasized that according to its wording, LAU's *main conclusion*, that traction gives the best primary radiological results and thereby the most favourable late clinical results, is in accurate agreement with J M 's evaluation

The disagreement concerns only *how much better* the results are after traction

J M of course feels that the predictions concerning the late clinical results of the three methods of treatment found in the present study have better foundations and therefore will come true But the final decision must await the very late follow up examinations – and even from such examinations it is empirically difficult to form a definite opinion, cf Postscript p 71

Table 20 Radiological results of wheelchair and traction treatments in the ♂A II groups of the series assessed by % "SPH" and by % "excellent" (LAU) ("NORM sph" J M), calculated on the basis of Lauritzen's as well as of J M's measurements

The ♂A II group of the Wh series includes only patients whose treatment had been carried out, according to Lauritzen, "perfectly" or "well" In the Tr series the ♂A II groups include only patients whose Tr treatment has been carried through for 12 months or longer

		% "SPH"	No of pts.	% "Excellent"[1]) equal to % "NORM sph"[2])	No of pts
LAU's measurements	Wh treatment of the ♂A II group of the Wh series carried out "perfectly" or "well"	88 %	(28/32)	58 %	(21/36)
	Tr treatment of the ♂A II group of the Tr series carried out ≥12 mo	100 %	(17/17)	[illegible]9 %	(16/18)
J M's measurements	Wh treatment of the ♂A II group of the Wh series carried out "perfectly" or "well"	80 %	(28/35)	49 %	(17/35)
	Tr treatment of the ♂A II group of the Tr series carried out ≥12 mo	100 %	(25/25)	92 %	(23/25)

[1]) (LAU), [2]) (J M)

128–129) as I did on the basis of my conclusion

The result of traction *is* better than that of the other two methods of treatment.

On the other hand, there is not agreement as to *how much better*

By the use of J M's criterion it will be found, for instance, that *traction* treatment of a series composed like the wheelchair series gives a satisfactory result in about 60 % more patients than does *wheelchair* treatment (with traction 76 % "NORM sph", with wheelchair treatment 47 % "NORM sph") – according to LAU's criterion in about 7 % (with traction 91 % "SPH", with wheelchair treatment 85 %) This corresponds to LAU's evaluation that the result of traction is "slightly better" than that of wheelchair treatment)

As regards the corresponding differences in other groups of patients, using LAU's as well as J M's measurements, cf Diagram 30 a, ♂ b, ♂ c, and Table 20

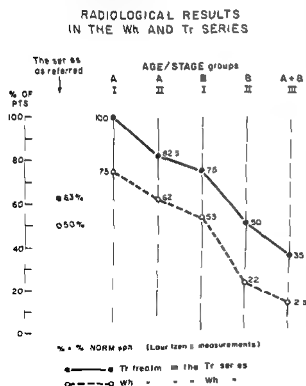

Diagram 32 Radiological results – only % "NORM sph" – in the Wh and Tr series as referred and in the age/stage groups of these series calculated using Lauritzen's radiological measurements

For comparison cf Diagram 4 The corresponding radiological results calculated using J M's radiological measurements

(Abbreviations and symbols cf survey p 12 No of pts cf Appendix, Table 26)

Thus, LAU's optimistic evaluation of the clinical sequelae in group "SPH" leads to an underestimate of the difference between the efficacy of traction and wheelchair treatment – and thereby to recommendations for treatment differing from those in the present publication. LAU states, for instance, in his thesis p. 129, that it is relatively immaterial how the patients of the oldest and youngest age group are treated, the results of traction not being essentially superior to those of wheelchair treatment. In only one, special group of patients in the middle age group does LAU feel that traction is a definite advantage.

The use of J.M.'s criterion of a good result – % "NORM sph" – gives the results in the age/stage groups as shown in Diagram 4 (J.M.'s measurements). In all age/stage groups there is an appreciable difference in the results between wheel-chair and traction treatment. This difference is moreover accentuated in the oldest and especially the youngest age group when using LAU's own measurements (Diagram 32).

The conclusion drawn from these results must be that as a general rule all age groups – also the oldest and youngest – should be treated by traction. (Of course, individual contra-indications may exist.)

In brief: The two examiners LAU and J.M. measured the X-ray films with identical results – but evaluated the clinical consequences of the radiological results differently.

However, it must be emphasized that according to its wording, LAU's main conclusion, that traction gives the best primary radiological results and thereby the most favourable late clinical results, is in accurate agreement with J.M.'s evaluation.

The disagreement concerns only *how much better* the results are after traction.

J.M. of course feels that the predictions concerning the late clinical results of the three methods of treatment found in the present study have better foundations and therefore will come true. But the final decision must await the very late follow-up examinations – and even from such examinations it is empirically difficult to form a definite opinion, cf. Postscript p. 71.

Table 20 Radiological results of wheelchair and traction treatments in the ♂A II groups of the series, assessed by % "SPH" and by % "excellent" (LAU) ("NORM sph " J M), calculated on the basis of Lauritzen's as well as of J M 's measurements

The ♂A II group of the Wh series includes only patients whose treatment had been carried out, according to Lauritzen, "perfectly" or "well" In the Tr series the ♂A II groups include only patients whose Tr treatment has been carried through for 12 months or longer

		% "SPH"	No of pts	% "Excellent"[1]) equal to % "NORM sph "[2])	No of pts
LAU's measurements	Wh treatment of the ♂A II group of the Wh series carried out "perfectly" or "well"	88 %	(28/32)	58 %	(21/36)
	Tr treatment of the ♂A II group of the Tr series carried out ≥12 mo	100 %	(17/17)	89 %	(16/18)
J M 's measurements	Wh treatment of the ♂A II group of the Wh series carried out "perfectly" or "well"	80 %	(28/35)	49 %	(17/35)
	Tr treatment of the ♂A II group of the Tr series carried out ≥12 mo	100 %	(25/25)	92 %	(23/25)

[1]) (LAU), [2]) (J M)

128–129) as I did on the basis of my conclusion

The result of traction *is* better than that of the other two methods of treatment

On the other hand, there is not agreement as to *how much better*

By the use of J.M 's criterion it will be found, for instance, that *traction* treatment of a series composed like the wheelchair series gives a satisfactory result in about 60 % more patients than does *wheelchair* treatment (with traction 76 % "NORM sph ", with wheelchair treatment 47 % "NORM sph ") – according to LAU's criterion in about 7 % (with traction 91 % "SPH ", with wheelchair treatment 85 %) This corresponds to LAU's evaluation that the result of traction is "slightly better" than that of wheelchair treatment)

As regards the corresponding differences in other groups of patients, using LAU's as well as J M 's measurements, cf Diagram 30 a, ♂ b, ♂ c, and Table 20

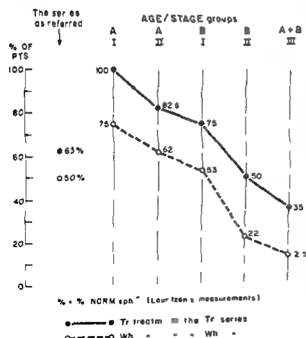

Diagram 32 Radiological results – only % NORM sph " – in the Wh and Tr series as referred and in the age/stage groups of these series calculated using Lauritzen's *radiological measurements*

For comparison cf Diagram 4 The corresponding radiological results calculated using J M 's radiological measurements.

(Abbreviations and symbols, cf survey p 12 No of pts cf Appendix, Table 26)

Thus LAU's optimistic evaluation of the clinical sequelae in group "SPH" leads to an underestimate of the difference between *the efficacy of traction* and wheelchair treatment – and thereby to recommendations for treatment differing from those in the present publication LAU states, for instance, in his thesis p 129, that it is relatively immaterial how the patients of the oldest and youngest age group are treated, the results of traction not being essentially superior to those of wheelchair treatment In only one, special group of patients in the middle age group does LAU feel that traction is a definite advantage

The use of J M 's criterion of a good *result – % 'NORM sph" – gives the* results in the age/stage groups as shown in Diagram 4 (J M 's measurements) In all age/stage groups there is an appreciable difference in the results between wheel chair and traction treatment This difference is moreover, accentuated in the oldest and especially the youngest age group when using LAU s own measurements (Diagram 32)

The conclusion drawn from these results must be that as a general rule all age groups – also the oldest and youngest – should be treated by traction (Of course, individual contra indications may exist)

In brief The two examiners LAU and J M measured the X ray films with identical results – but evaluated the clinical consequences of the radiological results differently

However, it must be emphasized that according to its wording, LAU's *main conclusion* that traction gives the best primary radiological results and thereby the most favourable late clinical results, is in accurate agreement with J M 's evaluation

The disagreement concerns only *how much better* the results are after traction

J M of course feels that the predictions concerning the late clinical results of the three methods of treatment found in the present study have better foundations and therefore will come true But the final decision must await the very late follow up examinations – and even from such examinations it is empirically difficult to form a definite opinion, cf Postscript p 71

Table 20 Radiological results of wheelchair and traction treatments in the ♂A II groups of the series assessed by % "SPH" and by % "excellent" (LAU) (NORM sph " J M), calculated on the basis of Lauritzen s as well as of J M s measurements

The ♂A II group of the Wh series includes only patients whose treatment had been carried out according to Lauritzen, 'perfectly' or 'well' In the Tr series the ♂A II groups include only patients whose Tr treatment has been carried through for 12 months or longer

		% "SPH"	No of pts.	% 'Excellent"[1]) equal to % 'NORM sph "[2])	No of pts.
LAU's measurements	Wh treatment of the ♂A II group of the Wh series carried out 'perfectly" or "well'	88 %	(28/32)	58 %	(21/36)
	Tr treatment of the ♂A II group of the Tr series carried out ≥12 mo	100 %	(17/17)	89 %	(16/18)
J M 's measurements	Wh treatment of the ♂A II group of the Wh series carried out 'perfectly" or "well"	80 %	(28/35)	49 %	(17/35)

[1]) (LAU), [2]) (J M)

128–129) as I did on the basis of my conclusion

The result of traction *is* better than that of the other two methods of treatment

On the other hand, there is not agreement as to *how much better*

By the use of J M 's criterion it will be found, for instance, that *traction* treatment of a series composed like the wheelchair series gives a satisfactory result in about 60 % more patients than does *wheelchair* treatment (with traction 76 % "NORM sph ", with wheelchair treatment 47 % "NORM sph ") – according to LAU's criterion in about 7 % (with traction 91 % "SPH ", with wheelchair treatment 85 %) This corresponds to LAU's evaluation that the result of traction is "slightly better" than that of wheelchair treatment)

As regards the corresponding differences *in other groups of patients* using LAU's as well as J M 's measurements, cf Diagram 30 a, ♂ b, ♂ c, and Table 20

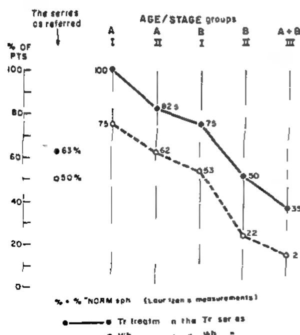

Diagram 32 Radiological results – only % NORM sph – in the Wh and Tr series as referred and in the age/stage groups of these series calculated using Lauritzen s *radiological measurements*

For comparison cf Diagram 4 The corresponding radiological results calculated using J M s radiological measurements.

(Abbreviations and symbols cf survey p 12 No of pts cf Appendix Table 26)

Thus, the larger this group in a treated series, the better the result

But now it was discovered that the three series differed mutually with regard to *factors,* apart from the treatment, *which affect the radiological result* In other words Differences in the radiological results between the three series reflected not only differences in the efficacy of the treatment, but also differences in the nature of the series

Three factors were operative

1 The *stage of the disease* at the institution of treatment The earlier the stage, the better the result
2 Patient *age* at institution of treatment The younger, the better
3 *Sex* Boys attain – ceteris paribus – better results than girls

With regard to these three factors the wheelchair series proved to be more favourable than the other two, which did not differ much mutually

With a view to *eliminating the influence* of these three factors, the author picked out from each series a group – i e three in all – that was as far as possible uniform with respect to the named factors at the institution of the treatment (Designation ♂ A II – boys of the middle age group (II = 5–8 years) – who arrived for early treatment = A)

Now, the radiological result in these three groups of patients ought to afford a reliable picture of the *relative efficacy* of the three therapeutic methods

Only, there was a drawback of this means of evaluation, viz that the number of patients in each group was regrettably small (40, 20, and 27 pts)

However, this drawback could be remedied

Each series was divided into six age/stage groups (disregarding the sex ratio which was of minor importance) in the way that the cases in identically designated groups of the three series must be presumed to have a uniform prognosis prior to the institution of treatment

Thereafter, the efficacy of the three therapeutic methods in the these groups was analysed (Table 7, p 26)

By transferring, for instance, the percentage results in the groups of the traction series to the corresponding groups of the wheelchair series, it was possible to ascertain which result would be obtained by *traction treatment of a series composed like the wheelchair series*

Table 21 Radiological results – % NORM sph after 3 different methods of treatment (Wh BR and Tr)

A in three groups of patients having a uniform prognosis when referred (the ♂A II groups)

The differences between the results of Tr and Wh treatm. and between Tr and BR treatm in the groups are statistically significant ($p < 0.001$ and $p < 0.02$ respectively) (Cf also legend of Diagram 13 and survey in the Appendix Table 28)

B in a series composed like the Wh series.

B	Wheelchair treatment	Bed rest treatment in a total material composed like the wheelchair series	Traction treatment
	47 %	54 %	76 %

SUMMARY

An attempt was made to evaluate the efficacy of three non-operative methods in the treatment of Legg-Calvé-Perthes Disease (LCPD)

The criterion was the long-term clinical result

The following methods had been applied

1 Out-patient non-weightbearing in a *wheelchair* – duration about 2 years
2 Non-weightbearing in hospital by *bed rest without traction* for about 18 months, followed by ambulatory non-weightbearing for about 6 months – about 2 years in all
3 Non-weightbearing in hospital by *bed rest with traction* for about one year followed by bed rest without traction for about 6 months and another 6 months of ambulatory non-weightbearing – about 2 years in all

The starting point, and the basis of the study were three different series (comprising 114, 79, and 113 patients) each treated by one of the three methods

The late clinical result depends largely upon *the primary radiological result*

At first therefore, the radiological result of each treatment was described by measurements on X ray films and assessed according to the radiological joint deformity left by the disease The less the deformity of the femoral head, the better the radiological result Any joint deformities outside the femoral head were interpreted as secondary to the deformity of the head.

The procedure of measurement in a series was as follows

First the X-ray films were divided into *two groups* according to whether the femoral head, measured with Mose's plate, proved to be *spherical* or *non-spherical* The groups were designated "SPH " and "NON-sph " Therafter, the group "SPH " was sub-divided – according to fixed measuring criteria – into two groups normal spherical and pathological spherical called "NORM sph " and "PATH sph ", whose nature is apparent from the designations

According to the measurements on the X-ray films each series was thus divided into three groups of patients "NORM sph " "PATH sph ", and "NON-sph " according to the radiological shape and size of the femoral head

Without a knowledge of the clinical consequences of the joint deformities in the three groups of patients, the size of the group "NORM sph " was preliminarily considered a measure of the quality of the result According to the X ray films, it had to be assumed that only patients of this group would be likely to remain free of osteoarthritis

sensitive to changes in the *efficacy of the* treatment

Briefly, the main result of *the radiological* evaluation is

Application of the 3 methods in series composed like the wheelchair series (or like the bed rest or the traction series) gives on treatment with *traction* $1^1/_2$ times as *many* satisfactory (and only half as many poor) radiological results as bed rest or *wheelchair* treatment

(*Two examiners* measured the radiological deformities, *quite independently* of each other Calculation of the radiological results on the basis of these two sets of measurements gave practically the same result (cf p 78, in particular Diagram 30))

What now are the *clinical consequences* of these radiological results?

Perusal of 19 previous reports on more or less *late follow-up studies of* LCPD *series* treated by different methods revealed that radiological and clinical osteoarthritis was observed first and foremost in radiological group "NON sph" and in small numbers, *but indubitably* also in group "SPH" (presumably only in "PATH sph") – in the latter *it is true*, not until the patients had reached a mean age of about 40

Later follow-up studies of LCPD series are not available at present (yet vide infra)

The preliminary estimate that *only the group NORM sph' would remain free of osteoarthritis* (at least up to the mean age of 40) *was thus confirmed*

At the same time, however, the investigation had shown that the cases of osteoarthritis that were found were mild and thus did not cause essential complaints – only about one-third of the arthritic patients being more or less "disabled"

Now *the problem was to ascertain the* prognosis *beyond the latest follow up study* at a mean age of 40

Direct studies of LCPD series beyond this age were *not* available However, investigation of large series of cases with secondary osteoarthritis – comprising also secondary osteoarthritis following upon *diseases* other than LCPD – showed in retrospect that in general secondary osteoarthritis *develops* according to a fairly uniform *pattern*, regardless of the nature of the *primary disease*

The first symptom appeared

in 1/3 of the cases before the age of 40,
in 1/3 of the cases between 40 and 50,
in 1/3 of the cases after the age of 50.

The *time schedule* shifts somewhat In the *event of severe joint deformities* the osteoarthritis sets in earlier – *in more* cases before the age of 40 – and in the event of *mild* deformities later – in more cases after 50

The largest material of osteoarthritis from which these data can be deduced is *Ruelle's (1961)* Indeed, it also proved a good exponent for the result of the studies *of* others (*Jerre 1950, Wiberg 1939, Danielsson 1964*, Lloyd Roberts 1955, Lance 1937, and others)

Ruelle's material comprises 271 patients *who applied for treatment* of secondary osteoarthritis due to different causes. (Thus, the rate of osteoarthritis in his material is 100 %)

The time of onset of clinical symptoms of osteoarthritis (joint pain, joint stiffness) could be mapped in retrospect with reasonable accuracy Thus, it was possible to ascertain the percentage of the total cases of osteoarthritis developing prior to the 30th year of age and thereafter in the age groups 30–40, 40–50, 50–60, etc Thereby, a total picture of the development of osteoarthritis could be obtained

This picture applies to Ruelle's mixed series, but the values can be used also for drawing a picture of the development of osteoarthritis in pure LCPD series – provided that the deformities in these series, with respect to arthritogenic effect, are comparable *with those in Ruelle's total*, mixed material or with those *in one of his* special groups Of course, they are not

(For a total survey of the radiological results cf Appendix, Table 27 Abbreviations and symbols on p 12)

In other words, it was possible to determine the efficacy of the three methods in the same total material (e g the wheelchair series) and thereby obtain a wider statistical basis Thus, the inaccuracy in the individual smaller groups ought to be equalized to a certain extent

The result of this method for determining the radiological efficacy of the three forms of treatment is shown in Table *21 B*

For comparison Table *21 A* sets out the result of the evaluation performed in the three small uniform groups of patients (♂ A II) (cf also Diagram 33)

The reason why the difference in efficacy between the therapeutic methods is less marked in a total material than in the small uniform groups of patients is that a total material comprises cases with a very favourable and others with a very unfavourable prognosis groups in which the results will be, broadly speaking and regardless of the treatment, *good or poor* respectively In the small uniform groups of patients, on the other hand, all cases are

series, as the age distribution and joint deformity could be determined more precisely To avoid the effect of the different severity in the three series, the development of osteoarthritis may be calculated int al as it would be after the use of the three therapeutic methods in three quite identical series composed like the wheelchair series

Diagram 34 gives the result of these calculations, whose absolute presuppositions are the preceding sections on radiological and clinical evaluation

This diagram sets out, in a perspicuous way, *the main result of the present study*

The relative clinical efficacy of the three therapeutic methods in identical series of *known composition* – compared with the results of less effective methods in less known series

The relative – and absolute – efficacy of the three methods may be worded as follows

If a series of LCPD, of approximately the same composition as the "wheelchair series", is referred through a period of time to an orthopaedic department in this country the radiological joint deformities left after the treatment, be it *wheelchair*, bed rest or traction treatment, will be so mild that no essential number of cases of clinically significant osteoarthritis will develop before the patients have attained the mean age of about *40* (cf also Diagram 28)

But after that *age the development* of osteoarthritis gains impetus At a mean age of about *50* almost *one third* of the surviving patients must be expected to have applied for treatment of osteoarthritis after *wheelchair treatment* rather more than *one-quarter* after *bed rest treatment* and about *one-seventh* after *traction treatment*

Thereafter *the development* is slower After *wheelchair and bed rest* treatment osteoarthritis develops *in a maximum* of *one half* of the patients after *traction* in *one quarter* – and this *maximum* is not reached until the age of almost 70

In other words the number of patients who sooner or later have to apply for treatment of secondary osteoarthritis *after traction* is only half that after *wheelchair* treatment and *bed rest treatment* But the number of patients with osteoarthritis among the survivors does not reach a magnitude of essential importance, after all forms of treatment, until the patients have reached the mean age of *50*

In the present publication attention has constantly been drawn to the numerous pitfalls encountered while performing the calculations and the general uncertainty attaching to them

Therefore, the apparently very precise predictions can only be taken with considerable reserve

Only the ratio between the values will presumably stand its test at late follow up studies (about the year of 2025)[1]

Several clinicians and child psychologists have claimed that the better results of traction therapy are too dearly bought by the long hospital treatment away from home

On the basis of considerable experience, the present author does not agree – provided that the treatment is carried out in a suited institution (Appendix, Comment 1)

The reason why ambulatory forms of treatment are preferred, despite their indubitably poorer somatic results, is most probably that such well-suited institutions are not available everywhere

After completion of the study reported above, a *further follow-up examination* (in collaboration with Mose et al) *was performed in 1974 of Helbo s previously followed patients* Regrettably only 25 could be traced These patients had at that time a follow up period of *more than 50 years*

According to *calculations* it would be expected that almost *90 %* of the patients surviving in 1974 would have applied for treatment because of osteoarthritic symp

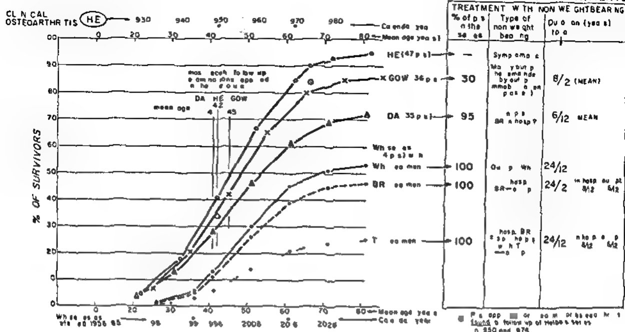

Diagram 34 Expected *development of osteoarthritis (presented for treatment) in the series of Helbo Gower & Johnston and Danielsson & Hernborg calculated by using figures from Ruelle s total material (I +II) and in 3 ident cal series composed like the Wh series having Wh BR or Tr treatment calculated by using figures from Ruelle s group II c*

% % of survivors at the mean ages and calendar years stated

For comparison the diagram gives the actual *% of survivors in Helbo s series who had applied for treatment of osteoarthritis at follow up in 1950 and 1974*

On the right of each series the % of patients in the series concerned who had received treatment *by non weightbearing – and the type of such treatment (in patient/out patient) as well as its duration*

I preferred showing the development of osteoarthritis with Wh BR and Tr treatment in 3 series composed l ke the Wh series as this clearly sets out the relative efficacy of the 3 treatments – the main problem of the present study

If the three curves at the bottom illustrated the development of osteoarthritis in the 3 series as referred their shape and situation would be affected by the fact that at institution of treatment the Wh series was prognostically more favourable than the BR and Tr series

The development of osteoarthritis in the Wh BR and Tr series as referred is shown in Table 18

directly commensurable but the comparison used ought to be reasonably probable

Knowing fairly well the maximum possible percentage of osteoarthritis in an LCPD series (e g the size of the groups ' PATH sph ' + ' NON sph) one can determine by the aid of Ruelle's figures the percentage of patients who have applied for treatment of osteoarthritis at a given time – provided that the age distribution at that time is known (Appendix Comment 5)

This possibility was first utilized for calculating by the aid of Ruelle s figures the expected osteoarthritis rate *at the time of follow up* in 3 of the latest follow up studies of LCPD series – Helbo s Gower & Johnston s and Danielsson & Hernborg s Thereafter the calculated and actual values were compared

As this showed reasonable agreement between the *calculated* and *actual* value it was felt justified to carry the calculations further into the future and fix the expected osteoarthritis rate 10 20 and 30 years after the latest follow up

At last the author arrived at *the central problem* The future development of osteoarthritis in the *wheelchair bed rest* and *traction series* which had been observed only up to the time of primary healing These calculations were carried out – and could even be carried out with greater accuracy than in the above mentioned

series as the age distribution and joint deformity could be determined more precisely To avoid the effect of the different severity in the three series, the development of osteoarthritis may be calculated inl al as it would be after the use of the three therapeutic methods in three quite identical series composed like the wheelchair series

Diagram 34 gives the result of these calculations, whose absolute presuppositions are the preceding sections on radiological and clinical evaluation

This diagram sets out, in a perspicuous way, *the main result of the present study*

The relative clinical efficacy of the three *therapeutic* methods in identical series of *known* composition – compared with the results of less effective methods in less known series

The relative – and absolute – efficacy of the three methods may be worded as follows

If a series of LCPD, of approximately the same composition as the "wheelchair series" *is referred* through a period of time to an orthopaedic department in this country the radiological joint deformities left after *the* treatment be it wheelchair, bed rest or *traction* treatment, will be so mild that no *essential number* of cases of clinically *significant osteoarthritis* will develop before *the patients* have attained the mean age of *about 40* (cf also Diagram 28)

But *after* that age the development of *osteoarthritis gains* impetus At a mean age of about *50* almost *one third* of the surviving patients *must be* expected to have applied for *treatment of osteoarthritis* after *wheelchair treatment* rather more than *one-quarter after bed rest treatment* and about *one seventh after traction treatment*

Thereafter the development is *slower* After *wheelchair and bed rest treatment* osteoarthritis develops in a *maximum* of *one-half* of the patients *after traction* in *one-quarter* – and this *maximum* is not reached until the age of almost 70

In other words the number of patients who sooner or later have to apply for treatment of secondary osteoarthritis *after traction* is only half that after *wheelchair* treatment and *bed rest treatment* But the number of patients with osteoarthritis among the survivors does not reach a magnitude of essential importance, after all forms of treatment, until the patients have reached the mean age of *50*

In the present publication attention has constantly been drawn to the numerous pitfalls encountered while performing the calculations and the general uncertainty attaching to them

Therefore, the apparently very precise predictions can only be taken with considerable reserve

Only the ratio between the values will presumably stand its test at late follow-up studies (about the year of 2025)'

Several clinicians and child psychologists have claimed that the better results of traction therapy are too dearly bought by the long hospital treatment away from home

On the basis of considerable experience, the present author does not agree – provided that the treatment is carried out in a suited institution (Appendix, Comment 1)

The reason why ambulatory forms of treatment are preferred, despite their indubitably poorer somatic results is most probably that such well-suited institutions are not available everywhere

COMMENT 1

Normal' Range of the Quotients

"The normal range of the epiphyseal quotient" is usually interpreted as the variation of the epiphyseal quotient *in normal children* – with normally shaped femoral heads – and thus the expression *can* be interpreted

However, normally shaped femoral heads are found not only in *normal children* but also in sick children, even in children with a history of hip disease – e g in *children with sequelae to LCPD*

But it is the variation in cases with normally shaped femoral heads which is of interest in our context Therefore, the term "normal range of the epiphyseal quotient" is interpreted here in a somewhat wider sense viz as

The variation *of the epiphyseal quotient in children with normally shaped femoral heads*

However the normal range of the epiphyseal quotient' in this sense is not the same in a series of normal children and in a series of children having sequelae to LCPD In *normal children* all of whom have normally shaped femoral heads the epiphyseal quotients come down to 85 In an *LCPD series* the epiphyseal quotients, in cases with *normally shaped femoral heads,* come down as far as 60 (*All* cases with epiphyseal quotient >60 – *and only these* – have normally shaped femoral heads)

Therefore, the term "normal range of the epiphyseal quotient" is used in the present paper only in the special sense

Range of the epiphyseal quotient in children with normally shaped femoral heads in an LCPD series

It is only a knowledge of this range which is of interest in evaluating the therapeutic results in an LCPD series

The range of the *joint surface quotient* in LCPD patients with normally shaped femoral heads and the range of the *radius quotient* in LCPD patients with femoral heads of normal shape and size, on the other hand, are equal to the ranges in normal children (>85 and <115 respectively)

Thus, in an LCPD series the quotients are "within the normal range" when the *epiphyseal quotient >60* the *joint surface quotient >85* and the *radius quotient <115*

COMMENT 2

Comparison of the Evaluations of Radiological Results of Treatment by 1 Measuring Method ("1-quotient assessment") and by a Combination of 3 Measuring Methods ("3-quotient assessment")

In the present study the radiological assessment was done by dividing the series into three groups of patients 'NORM sph" PATH sph' and "NON-sph"

First the series were divided by the aid of Mose s plate into two groups – 'SPH" and 'NON-sph" Thereafter, "SPH" was sub-divided into two groups "NORM sph" and "PATH sph" by means of *three* measuring methods determining three quotients for each patient joint surface quotient epiphyseal quotient, and radius quotient

ment using 'SPH.", the results appear to be better (higher percentages) and the differences between the therapeutic methods get less marked than in the stricter 3-quotient assessment

These *differences* are easy to spot, but the *similarity* of the results found by the four assessments is perhaps even more *striking* The four diagrams (I–IV) are of a striking uniformity, all showing considerably better results of traction than of wheelchair or bed rest treatment, and the differences between these therapeutic results are at least of approximately the same magnitude with all four evaluations

The reason why the more complicated "3-quotient assessment" was preferred in the present study is that it is more reliable

Three criteria secure much better than one that cases singled out as "NORM sph" really live up to their name With the use of 1 criterion the most peculiar femoral heads may at times slip into the group

Besides, the effect of special difficulties of measurement and other sources of error attaching to the individual measuring methods will be to some extent equalized by a combination of three measuring methods

Nevertheless, the "1-quotient assessment" may be highly applicable as an easy, preliminary orientation at primary healing

For such assessment the radius quotient is perhaps best suited In the first place, measurement of the radius quotient is so simple that the risk of measuring errors must be less than in the other, more complicated methods. In the second place, it is apparent from Diagrams 35 and 36 that the results of assessing by this quotient alone is – quantitatively – closest to the results of the "3-quotient assessment" The slight difference is due to the fact that, apart from the cases in "NORM sph", the "NORM sph" (RA) comprises cases with a change in the shape of the head without any increase in growth

However, it is a presupposition for using the radius quotient that the *age distribution* and *follow-up periods* are *approximately the same* – as in the present series. *And thus is a demand which is not so easy to fulfill*

But if this condition is fulfilled, the measurements needed for this 1-quotient assessment must be said to be very simple A basis for an evaluation is obtainable merely by placing Mose's plate over the femoral head on the X-ray film and recording the length of the radius for the spherical heads

It can hardly be simpler

The above may perhaps urge busy clinicians to attempt a *preliminary* evaluation of their therapeutic results However, it must be emphasized that the 3-quotient

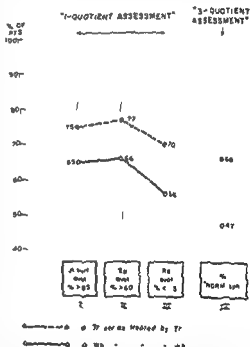

Diagram 36 Results in the Wh and Tr series as referred assessed by 1 measuring method – "1-quotient assessment (I II III) and by a combination of 3 measuring methods – "3-quotient assessment" (IV)

I Assessment by the joint surface quotient
II Assessment by the epiphyseal quotient
III Assessment by the radius quotient
IV Assessment by a combination of all 3 measuring methods – % NORM sph

This diagram is a more instructive and perspicuous edition of Diagram 35 (omitting the BR results)

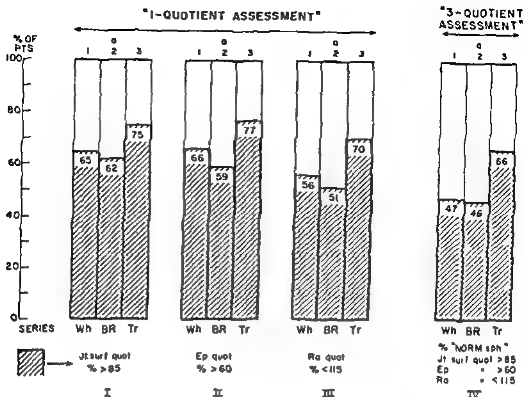

Diagram 35 Results in the series as referred (a) assessed by only one measuring method – "1-quotient assessment" – and by a combination of 3 measuring methods – "3-quotient assessment"

a { 1 Wh series as referred (114 pts) treated by Wh, 2 BR series as referred (79 pts) treated by BR 3 Tr series as referred (113 pts) treated by Tr

I Assessment by the joint surface quotient,
II Assessment by the epiphyseal quotient
III Assessment by the radius quotient
IV Assessment by a combination of all 3 measuring methods – % "NORM sph"

Tables 22, 23, and 24 in the Appendix set out the joint surface epiphyseal, and radius quotients in the three series

When all three were within the normal range, the case was assigned to "NORM sph"

This sounds fairly complicated – and may indeed deter a clinician who wants to assess his results

Considerable simplification would be obtained by performing the assessments exclusively by the aid of *one* quotient instead of three

Diagram 35 gives the results in the three series as referred, when the cases with normally spherical heads are singled out by using 1 quotient (I–II–III) and by using 3 quotients (IV)

It will be seen that the results of the "1-quotient assessment" are on a higher level than those of the "3-quotient assessment" and that the differences between the results in the three series appear to be less marked This is particularly evident from Diagram 36 which shows the results only for the wheelchair and traction series Diagram 35 shows that this pattern may be broken The differences between the bed rest and wheelchair results in the 3-quotient assessment are less marked than expected

These differences between the results of "1-quotient assessment" and "3-quotient assessment" are naturally explained by the fact that in the "1-quotient assessment" the demands on a satisfactory result have been reduced Therefore, as in the assess-

second follow up 12 years later was somewhat less pronounced (Ratliff's second publication), the percentage of "SPH" was fixed as about 48 % – somewhat higher than the percentage of practically speaking normal heads in this selected group of patients about 44 %.

COMMENT 4

"Spread". Fixing the Percentage of the 19 Series Over Which Cases of Radiological Osteoarthritis and Subjective Arthritic Symptoms Spread, When the Series Are Arranged by Increasing Primary Joint Deformity – e g as in Diagram 18 – from Left to Right

For each series, then, two spread rates are to be fixed – one for radiological osteoarthritis and one for subjective symptoms.

Below, the procedure in the five series with longest follow-up will be described In principle, it is the same as in fixing the "spread rate" in the remaining 14 series, but space does not permit a detailed description of the procedure in these 14 series

In the five series, thus, there are 10 spread rates to fix

Series No 1 Helbo

(a) *Radiological osteoarthritis* 56 % of the patients exhibited signs of radiological osteoarthritis According to Helbo himself, these 56 % were distributed ("spread") over two of the groups into which he divided his material and classified by him – according to the primary radiological deformity – as "greatly flattened" and "irreg." On the other hand, Helbo found no signs of radiological osteoarthritis in his third group designated "spherical" The two groups "greatly flattened" and "irreg." combined make up 88 % of the total series Accordingly, the 56 % patients having radiological osteoarthritis are "spread" over 88 % of the series

In other words, the spread rate of radiological osteoarthritis is *apparent direct from Helbo's data.*

(b) *Subjective symptoms.* The spread rate of such symptoms is found on the basis of exactly the same reasoning as that of radiological osteoarthritis 62 % of the patients had symptoms (mostly joint pain), distributed – like the signs of radiological osteoarthritis – over 88 % of the series, whereas 12 % (the group "spherical") were symptom free

For the remaining 4 series a total of 8 "spread rates" have to be determined

Thereamongst 5 can be determined as in Helbo's series, *directly on the basis of data given by the four authors*

However, a comment is required with respect to series No 3, (Gower & Johnston's) In this series radiological osteoarthritis and subjective symptoms were found to be "spread" over *all* groups, although in the "round" group with least deformity there was only one patient with radiological osteoarthritis and one with subjective symptoms (pain), i e each making up one-sixth of this group The "spread" in this group, then, was taken to be one-third – giving a "spread rate" for the entire series of 86 %

The last three spread rates in these four series cannot be determined *direct* on the basis of information given by the authors, the percentage of osteoarthritic patients being stated only for the total series – not for individual groups

method used in the present study is more reliable – and it sets out the difference in the efficacy of the treatments better than do the less strict I-quotient assessments At least, this has been observed in the present three series

COMMENT 3

Fixing %"SPH " in Series Nos. 1–5 Seen at Follow-up (Helbo, Sundt II, Gower & Johnston, Danielsson & Hernborg, and Ratliff)

Series No 1 The percentage of "SPH." in Helbo's series was fixed as about *12–13 %*

Helbo and I have previously used the same measuring methods for evaluating the therapeutic result in one series treated by bed rest and have thereby arrived at the same result (Meyer 1966) Accordingly, I was able to evaluate Helbo's classification of his series This showed that the groups "greatly flattened" and "irregular" combined correspond to my group "NON-sph ", whereas his group "spherical" corresponds to my "SPH " – which makes up about 12 5 % of his total series

Series No 2 The percentage of "SPH " in Sundt's series was estimated at *about 27 %*

According to the text of Sundt's paper the group "spherical" corresponds approximately to my "NORM sph " The group "ovoid" is *characterized* as "favourably healed" As Sundt cannot have used this term for cases which had healed with irregular non-spherical heads (the group "NON-sph "), which are invariably greatly deformed at least the greater part of his cases in the "ovoid" group must belong to "SPH " To arrive at a minimum value only half the "ovoid" group was assigned to "SPH " which thus makes up about 27 % of the total series (between 20 35 %)

Series No 3 The percentage of "SPH " in Gower & Johnston's series was estimated at *about 30 %* This assessment is uncertain According to the X-ray films shown (and the group designation) the cases of the "round" group (20 %) correspond to the better part of "SPH " (approximately to "NORM sph ") It is difficult to say how many of the large group "flattened" (73 %) have "poorly" spherical heads with a long radius I have calculated 10/73 "SPH " in this group – presumably too low Thus, out of the entire series "SPH " ought to make up (at least) 30 %

Series No 4 The percentage of "SPH " in Danielsson's and Hernborg's series was estimated at *about 35 %* Their classification is illustrated by 4 X-ray films showing the least deformed joint of each group According to the appearances there is no doubt that group "0" and at least part of the cases in group "I" have healed with spherical heads ("SPH ") Judging by the X-ray films (and the small drawings from the films of each case) it may be estimated that 3/4 of the cases in group "I" belong to "SPH " so that the percentage of "SPH " in the entire series is about 35 %

Series No 5 The percentage of "SPH " in Ratliff s series was estimated at *about 48 %* His series is not classified according to purely radiological but according to a *combination of radiological and clinical* criteria However it is explicitly mentioned in Ratliff's first publication that in 52 % of the cases the femoral head was "appreciably deformed" and in 40 % practically *normal* As the deformity of the heads in the selection of patients who were seen at a

cond follow-up 12 years later was somewhat less pronounced (Ratliff's second publication), the percentage of "SPH." was fixed as about 48 % – somewhat higher than the percentage of practically speaking normal heads in this selected group of patients about 44 %.

COMMENT 4

"Spread". Fixing the Percentage of the 19 Series Over Which Cases of Radiological Osteoarthritis and Subjective Arthritic Symptoms Spread, When the Series Are Arranged by Increasing Primary Joint Deformity – e g as in Diagram 18 – from Left to Right

For each series, then, two spread rates are to be fixed – one for radiological osteoarthritis and one for subjective symptoms

Below, the procedure in the five series with longest follow-up will be described In principle, it is the same as in fixing the "spread rate" in the remaining 14 series, but space does not permit a detailed description of the procedure in these 14 series

In the five series, thus, there are 10 spread rates to fix

Series No 1 Helbo

(a) *Radiological osteoarthritis* 56 % of the patients exhibited signs of radiological osteoarthritis According to Helbo himself, these 56 % were distributed ("spread") over two of the groups into which he divided his material and classified by him – according to the primary radiological deformity – as "greatly flattened" and "irreg." On the other hand, Helbo found no signs of radiological osteoarthritis in his third group designated "spherical" The two groups "greatly flattened" and "irreg " combined make up 88 % of the total series Accordingly the 56 % patients having radiological osteoarthritis are "spread" over 88 % of the series

In other words the spread rate of radiological osteoarthritis is *apparent direct from Helbo's data.*

(b) *Subjective symptoms.* The spread rate of such symptoms is found on the basis of exactly the same reasoning as that of radiological osteoarthritis 62 % of the patients had symptoms (mostly joint pain), distributed – like the signs of radiological osteoarthritis – over 88 % of the series, whereas 12 % (the group "spherical") were symptom free

For the remaining 4 series a total of 8 "spread rates" have to be determined

Thereamongst 5 can be determined as in Helbo's series, *directly on the basis of data given by the four authors*

However, a comment is required with respect to series No 3, (Gower & Johnston's) In this series radiological osteoarthritis and subjective symptoms were found to be "spread" over *all* groups, although in the "round" group with least deformity there was only one patient with radiological osteoarthritis and one with subjective symptoms (pain), i e each making up one sixth of this group The "spread" in this group, then, was taken to be one-third – giving a "spread rate" for the entire series of 86 %

The last three spread rates in these four series cannot be determined *direct* on the basis of information given by the authors, the percentage of osteoarthritic patients being stated only for the total series – not for individual groups

This applies to subjective symptoms in Sundt's series II and to radiological osteoarthritis as well as subjective symptoms in Ratliff's

SU_{II} Symptoms, in the form of *joint pain*, were found in 55 % of the patients of this series – i e , without spread in all patients of the groups "cylindrical" and "angular" (which total exactly 55 %) It is beyond doubt, however, that there must be a "spread" of patients with symptoms – and that this spread must then comprise at least half the group "ovoid" which makes up, together with the two groups mentioned above, 73 % of the entire series This is then the spread rate of subjective symptoms in the form of *joint pain* Since, however, the percentage of these subjective symptoms in the entire series is practically the same as that of radiological osteoarthritis (55 %/58 %), and since according to Sundt himself radiological osteoarthritis spread over the entire "ovoid" group, there is a predominant likelihood that the subjective symptoms, in the form of pain, also spread over the same area This is beyond doubt, if *a limp* is included among the subjective symptoms A limp was found in 67 % of the patients – far into the "ovoid" group True, a limp is not a sure sign of osteoarthritis, but at least it is a sequel to the primary LCPD, and a sequel which may be a great subjective strain on the patients

In accordance with these reflections, it is assumed that the subjective symptoms, like the radiological signs of osteoarthritis, were spread over *91 %* of Sundt's series

Ratliff In this series information is yielded only about the percentage of all patients in the series who had radiological osteoarthritis and subjective symptoms – 50 % and 20 % respectively These rates are only slightly lower than the percentages of the groups "fair" + "poor" and "poor" respectively The spread rates were therefore fixed as the size of these two groups of patients, i e 55 % and 23 % respectively In actual fact, however, they are presumably somewhat higher

As already mentioned, the spread rates in the other 14 series were determined according to exactly the same principles as those used for the five series with the longest follow-up periods

COMMENT 5

Ruelle's Figures and Their Use in Predicting the Development of Osteoarthritis in LCPD Series

Hip-deforming diseases – congenital or running their course during childhood – are followed by a certain number of cases of secondary osteoarthritis The percentage depends largely upon the extent of the joint deformities left by the disease

A material of such secondary osteoarthritis (271 patients presumably not selected according to age) following upon various hip deforming diseases has been analysed by *Ruelle* with a view to the age at which the osteoarthritis (subjective symptoms of osteoarthritis) set in

He found that

about 1/3 had started before the 40th birthday
about 1/3 had started between the 40th and 50th birthday
and 1/3 had started after the 50th birthday

lore detailed findings were that

100 %	had	developed	symptoms	of	osteoarthritis	before the	80th	birthday
99 %	"	"	"	"	"	"	70th	"
93 %	"	"	"	"	"	"	60th	"
70 %	"	"	"	"	"	"	50th	"
36 %	"	"	"	"	"	"	40th	"
10 %	"	"	"	"	"	"	30th	"
2 %	"	"	"	"	"	"	20th	"

These figures then refer to cases of osteoarthritis developing after the mixture of mild, moderate, and severe deformities present in Ruelle's total series – deformities probably on the average moderate In series with a larger number of mild deformities a smaller part of the cases of osteoarthritis – e g 1/5 – *will start* before *the 40th birthday* and a larger part, e g 1/2, *after the 50th* birthday The reverse will apply to series containing a larger number of severe deformities

Cf also the values listed for Ruelle's special groups (Table 12)

As already mentioned, Ruelle's cases of osteoarthritis were the sequelae to several different hip-deforming diseases However, the picture of the development of osteoarthritis might easily have been exactly the same if all the cases were sequelae to LCPD – provided that the hip deformities corresponded with respect to arthritogenic effect to those in Ruelle's series

We shall now follow from the time of primary healing an LCPD series in which the development of osteoarthritis occurs in conformity with the figures from Ruelle's *total* series and in which *all* patients are potential osteoarthritics

If the patients of such a series are examined say when they *pass their 40th birthday* the examination will show that about 1/3 of the total cases of osteoarthritis that will develop in the series have started before the 40th birthday

It is evident that if no patient died before the 40th birthday one third of the examined ("surviving") patients would have symptoms of osteoarthritis

But of course some patients – though few – die *before the 40th* birthday The majority will die without signs of osteoarthritis, and only a minority have had time to develop signs of osteoarthritis before dying – i e *they die with* osteoarthritis

Since, however, the mortality is the same in patients with and without osteoarthritis, the osteoarthritis rate among the survivors on the 40th birthday will be the same as if none had died

In other words

When 1/3 of the final number of cases of osteoarthritis set in before the 40th birthday, this means that 1/3 of the *survivors* have osteoarthritis at that time

The same rule – only using another fraction – naturally applies also if the examination has been carried out at any other age, e g 50, 60, or 70

(The *potential* osteoarthritic patients who *die before the expected osteoarthritis has developed* of course reduce the final rate of osteoarthritis

However, this reduction is not more than 4–6 % of the final cases In practice, this must be said to be immaterial considering the uncertainty of the deformity criteria by which the group of "final osteoarthritis" is selected In the *traction* series, for instance, there is a question of only 2 patients (cf Diagram 37))

"Final osteoarthritis" makes up a varying percentage of the patients in the various LCPD series – hardly ever 100 % as in the above example

Thus, if the final osteoarthritis rate is 60 % of the original series at primary

This applies to subjective symptoms in Sundt's series II and to radiological osteoarthritis as well as subjective symptoms in Ratliff's

SU_{II} Symptoms, in the form of *joint pain,* were found in 55 % of the patients of this series – i e, without spread in all patients of the groups "cylindrical" and "angular" (which total exactly 55 %) It is beyond doubt, however, that there must be a "spread" of patients with symptoms – and that this spread must then comprise at least half the group "ovoid" which makes up, together with the two groups mentioned above, 73 % of the entire series This is then the spread rate of subjective symptoms in the form of *joint pain* Since, however, the percentage of these subjective symptoms in the entire series is practically the same as that of radiological osteoarthritis (55 %/58 %), and since according to Sundt himself radiological osteoarthritis spread over the entire "ovoid" group, there is a predominant likelihood that the subjective symptoms, in the form of pain, also spread over the same area This is beyond doubt, if *a limp* is included among the subjective symptoms A limp was found in 67 % of the patients – far into the "ovoid" group. True, a *limp* is not a sure sign of osteoarthritis, but at least it is a sequel to the primary LCPD, and a sequel which may be a great subjective strain on the patients

In accordance with these reflections, it is assumed that the subjective symptoms, like the radiological signs of osteoarthritis, were spread over 91 % of Sundt's series

Ratliff In this series information is yielded only about the percentage of all patients in the series who had radiological osteoarthritis and subjective symptoms – 50 % and 20 % respectively These rates are only slightly lower than the percentages of the groups "fair" + "poor" and "poor" respectively The spread rates were therefore fixed as the size of these two groups of patients, i e 55 % and 23 % respectively In actual fact, however, they are presumably somewhat higher

As already mentioned, the spread rates in the other 14 series were determined according to exactly the same principles as those used for the five series with the longest follow-up periods

COMMENT 5

Ruelle's Figures and Their Use in Predicting the Development of Osteoarthritis in LCPD Series

Hip deforming diseases – congenital or running their course during childhood – are followed by a certain number of cases of secondary osteoarthritis The percentage depends largely upon the extent of the joint deformities left by the disease

A material of such secondary osteoarthritis (271 patients presumably not selected according to age) following upon various hip-deforming diseases has been analysed by *Ruelle* with a view to the age at which the osteoarthritis (subjective symptoms of osteoarthritis) set in

He found that

about 1/3 had started before the 40th birthday
about 1/3 had started between the 40th and 50th birthday
and 1/3 had started after the 50th birthday

More detailed findings were that

100 % had developed symptoms of osteoarthritis before the 80th birthday							
99 %	"	"	"	"	"	" 70th	"
93 %	"	"	"	"	"	" 60th	"
70 %	"	"	"	"	"	" 50th	"
36 %	"	"	"	"	"	" 40th	"
10 %	"	"	"	"	"	" 30th	"
2 %	"	"	"	"	"	" 20th	"

These figures then refer to cases of osteoarthritis developing after the mixture of mild, moderate, and severe deformities present in Ruelle's total series – deformities probably on the average moderate In series with a larger number of mild deformities a smaller part of the cases of osteoarthritis – e g 1/5 – will start before the 40th birthday and a larger part, e g 1/2, after the 50th birthday The reverse will apply to series containing a larger number of severe deformities

Cf also the values listed for Ruelle's special groups (Table 12)

As already mentioned, Ruelle's cases of osteoarthritis were the sequelae to several different hip-deforming diseases However, the picture of the development of osteoarthritis might easily have been exactly the same if all the cases were sequelae to LCPD provided that the hip deformities corresponded with respect to arthritogenic effect to those in Ruelle's series

We shall now follow, from the time of primary healing, an LCPD series in which the development of osteoarthritis occurs in conformity with the figures from Ruelle's *total* series and in which *all* patients are potential osteoarthritics

If the patients of such a series are examined say when they *pass their 40th birthday* the examination will show that about 1/3 of the total cases of osteoarthritis that will develop in the series have started before the 40th birthday

It is evident that if no patient died before the 40th birthday one-third of the examined ("surviving") patients would have symptoms of osteoarthritis

But of course some patients – though few – die before the 40th birthday The majority will die without signs of osteo arthritis, and only a minority have had time to develop signs of osteoarthritis before dying – i e they die with osteoarthritis

Since, however, the mortality is the same in patients with and without osteoarthritis, the osteoarthritis rate among the survivors on the 40th birthday will be the same as if none had died

In other words

When 1/3 of the final number of cases of osteoarthritis set in before the 40th birthday, this means that 1/3 of the *survivors* have osteoarthritis at that time

The same rule – only using another fraction – naturally applies also if the examination has been carried out at any other age, e g. 50, 60, or 70

(The *potential* osteoarthritic patients who *die before the expected osteoarthritis has developed* of course reduce the final rate of osteoarthritis

However, this reduction is not more than 4–6 % of the final cases In practice, this must be said to be immaterial *considering* the uncertainty of the deformity *criteria* by which the group of "final osteoarthritis" is selected In the *traction* series, for instance, there is a question of only 2 patients (cf Diagram 37))

"Final osteoarthritis" makes up a varying percentage of the patients in the various LCPD series – hardly ever 100 % as in the above example

Thus, if the final osteoarthritis rate is 60 % of the original series in primary

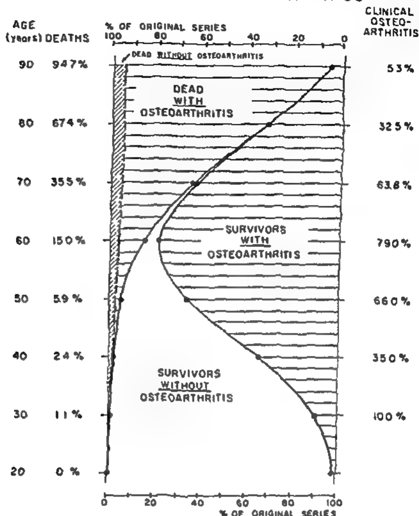

Diagram 37 Development of clinical osteoarthritis presented for treatment in an LCPD series in which all patients must be considered potential osteoarthritics because of the severity of the articular joint deformities

Calculation based upon Ruelle's total material (I + II)

The calculated osteoarthritis rates signify osteoarthritis in survivors when passing the listed birthday expressed in per cent of the "original" material at the age of 20 years

Mortality curve in relation to the age of 20 years Stat Årbog, Denmark 1968

From this diagram it is possible to read for each age (birthday)

% survivors without osteoarthritis,
% survivors with osteoarthritis,
% dead with osteoarthritis,
% dead without osteoarthritis – i e dead before clinical symptoms of osteoarthritis have appeared

healing, 20 % have started before the 40th birthday, and among the survivors 20 % have osteoarthritis (still using the figures of Ruelle's *total* matereal) With figures from Ruelle's less deformed groups, the percentage is <20 and with figures from his more deformed groups >20.

It was now attempted to *single* out such a group of "final osteoarthritis" — i e potentially osteoarthritic patients — from the *wheelchair, bed rest,* and *traction* series on the basis of the radiological deformity at primary healing All patients of the deformity groups "NON-sph" and "PATH sph" were assigned to this group

If a reasonably reliable estimate regarding the number of potential osteoarthritis at primary healing — and thereby regarding the final maximum osteoarthritis rate to be expected — has been made in an LCPD series, Ruelle's figures ought to be applicable, as described above, for predicting the osteoarthritis rate that will be found among the survivors at a given age

So far the discussion has concerned only the osteoarthritis rate at *a given age,* 40, 50, and 60, etc

To ascertain the osteoarthritis rate at a given time — e g at a possible follow-up examination — regard must be paid to the fact that in a given time the patients will differ in age Say, for instance, that the age distribution is from 40 to 50 at the time of followup, the number of patients with osteoarthritis among these survivors can be calculated with approximation by using the mean of the osteoarthritis rates at 40 and 50 (i e 53 % in deformities corresponding to those in Ruelle's total series and 100 % *final* osteoarthritis)

In extreme age groups, however, the mean cannot be used without correction

Of course, the same procedure is applicable when the age distribution is over *several* 10-year periods Only, in that event the calculated number of patients with osteoarthritis in each 10-year period must be added and related to the total number of surviving patients

This is the *procedure* used for the majority of the calculations in the clinical section — first to check the method in *series already seen at follow-up* (Helbo, Gower & Johnston, and Danielsson & Hemborg) and thereafter, when the method had proved reasonably applicable, for predicting the osteoarthritis rates at increasing mean ages, in the series already seen at follow-up as well as in those not yet followed up, viz the *wheelchair, bed rest and traction series*

Which are the degrees of severity of osteoarthritis to which Ruelle's figures refer?

It is characteristic of Ruelle's patients that all had, sooner or later, *applied for treatment* of osteoarthritis

Ruelle's series was divided into 10-year age groups according to the onset of osteoarthritis (20–30 years, 30–40 years, etc)

It seems likely that the *majority* of patients whose symptoms of osteoarthritis have set in within such a 10-year period have also applied for treatment before the expiry of this, relatively long period Only a *minority* develop their symptoms of osteoarthritis at such a late stage of the period that they have not applied for treatment before its expiry

If this is true at the expiry of the earliest 10-year period (e g. 20–30 years), it must be even more true of the osteoarthritis rates calculated at older ages The fact is that these calculations were based on patients with osteoarthritis from all the preceding 10-year periods — i e a number of patients increasing in the course of the years Since *all* patients from the preceding 10-year periods have gradually applied for treatment, the part — percentage — of patients who have *not* applied for treatment will *decrease in* the course of time — to a very low percentage

Thus, it appears *likely* that the majority of Ruelle's patients applied for treatment within the 10-year period in which their osteoarthritis set in However, we do not know this for certain, as Ruelle does not state the time interval between the onset of symptoms and the institution of treatment

Whether it is true depends upon whether Ruelle counts only *the time at onset of*

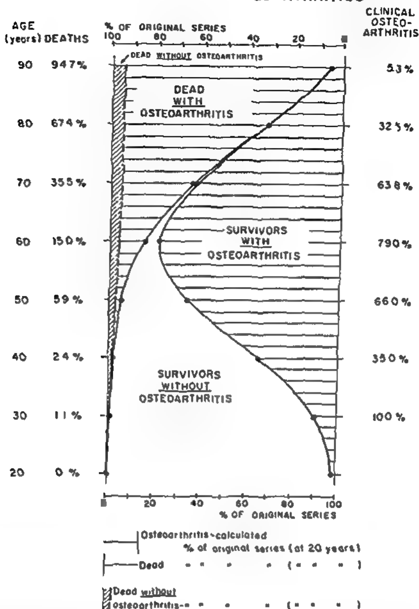

Diagram 37 Development of clinical osteoarthritis presented for treatment in an LCPD series in which all patients must be considered potential osteoarthritics because of the severity of the articular joint deformities

Calculation based upon Ruelle's total material (I + II)

The calculated osteoarthritis rates signify osteoarthritis in survivors when passing the listed birthday expressed in per cent of the "original" material at the age of 20 years

Mortality curve in relation to the age of 20 years Stat Årbog Denmark 1968

From this diagram it is possible to read for each age (birthday)

% survivors without osteoarthritis,
% survivors with osteoarthritis
% dead with osteoarthritis,
% dead without osteoarthritis – i e dead before clinical symptoms of osteoarthritis have appeared

healing, 20 % have started before the 40th birthday, and among the survivors 20 % have osteoarthritis (still using the figures of Ruelle's *total* matereal) With figures from Ruelle's less deformed groups, the percentage is <20 and with figures from his more deformed groups >20

osteoarthritis rate would correspond in all essentials to the percentage of osteoarthritis presented for treatment in Helbo's material (34 %), not to the higher percentage (62 %) of all cases of clinical osteoarthritis found by him

But which of Ruelle's groups is suited for such a calculation?

Ruelle's *total* material comprises patients with all kinds of primary deformity – mild as well as severe, but presumably predominantly severe – following upon congenital dislocation, subluxation, epiphysiolysis, and (a few) LCPD

Helbo's series, which consists of "untreated" LCPD cases, is also a predominantly severely deformed material

A priori it might be assumed, therefore,

the deformities in the special groups of patients closest to the middle epiphysiolysis LCPD, and subluxation)

Using the figures from Ruelle's total material for the calculation the rate, therefore, ought to correspond quite well to Helbo's percentage of osteoarthritis that had been presented for treatment and should preferably be *somewhat higher!*

Thus proved to be entirely true The calculated osteoarthritis rate was 41 %, the actual rate 34 %

Thus, the deformities in Ruelle's total material (RU I–II) seem to correspond well to those in Helbo's that is if Ruelle's values, as substantiated above, refer to patients who have applied for treatment of their osteoarthritic symptoms

The correctness of this supposition is also indicated by the following There is a striking difference in the percentage of clinical osteoarthritis found at follow-up examination of Helbo's series 62 % – and at follow-up examination of Danielsson & Hernborg's LCPD series – which was only 23 % It is striking because the mean age (and the age distribution at onset of the disease) is the same in both series and because the treatment of both series had been of little efficacy – (somewhat better in Danielsson & Hernborg's, viz 6 months' non-weightbearing against at most 3 months' in Helbo's)

On the other hand, the percentage of *radiological* osteoarthritis was approximately the same in both series Danielsson & Hernborg's *50 %* and Helbo's *56 %* This small difference is perhaps explicable by the somewhat more effective treatment of Danielsson & Hernborg's series – but this explanation can by no means account for the enormous difference between the clinical cases of osteoarthritis in the two very similar series

The only conceivable explanation is that Helbo's "clinical osteoarthritis" did not signify the same as Danielsson & Hernborg's, comprising a far larger number of mild cases than Danielsson & Hernborg's

Possibly, their criteria of clinical osteoarthritis do not differ much in theory, but in practice they function very differently Indeed it is (almost) impossible to set up a definite objective criterion of clinical osteoarthritis

Below, the term criteria refers exclusively to their function in practice

Thus Danielsson & Hernborg's criteria of clinical osteoarthritis appear to be far stricter than Helbo's

But plotting of 3 curves for the development of clinical osteoarthritis in three large series of predominantly *primary* osteoarthritis, reported by Ruelle, Danielsson, and Graber-Duvernay, shows that these curves practically coincide (Ruelle 1961, Danielsson 1964, Graber-Duvernay (quoted by Francon 1956) (Diagram 38))

This can in fact only be interpreted to the effect that the three authors *have had* the same criterion of "clinical osteoarthritis" – in particular that in practice Danielsson's and Ruelle's *has been* the same

However, the results of the follow up examination of secondary osteoarthritis

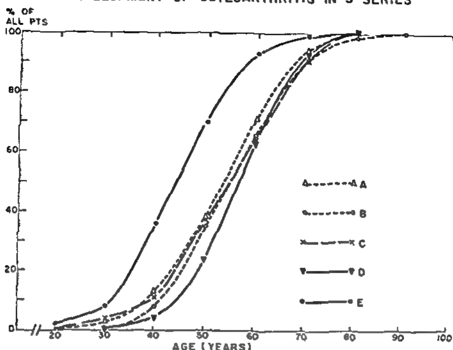

Diagram 38 Development of osteoarthritis in 5 different series of osteoarthritis affecting the hip
The points on the curves signify the percentage of cases of osteoarthritis causing symptoms before the age stated

A Primary + secondary osteoarthritis – Ruelle *(patient groups I, II, III, IV, and V), 924 pts, 1961*
B "Osteoarthritis" – presumably primary + secondary A Graber-Duvernay, *quoted by Francois Francon, 1067 pts, 1956*
C Primary + secondary osteoarthritis Danielsson *1964, 115 pts, data from patient list p 98*
D Primary osteoarthritis Ruelle *(patient groups III, IV, and V), 653 pts, 1961*
E Secondary osteoarthritis Ruelle *(patient groups I + II), 271 pts, 1961*

symptoms which really troubled the patient – and therefore rapidly led to treatment – or whether he included also the mildest symptoms – which a patient may have for years without applying for treatment

Ruelle's study is evidently an analysis *based upon case notes* (through several years) concerning the time at onset of osteoarthritis – and not the result of a follow-up examination Such an analysis is likely to afford information only about the onset of osteoarthritis symptoms which constitute a real complaint, and therefore have made the patient apply for treatment – and not about milder symptoms which the patient does not remember and to which he had not attached any importance

It is different with a *follow-up examination* in which even mild symptoms are easier to disclose by an interested and careful examiner

For instance, in Helbo's follow-up examination in 1950, when the patients' mean age was 42, 62 % had clinical symptoms of osteoarthritis, but only about half of these (34 %) had applied for treatment Helbo expressly states that the symptoms were very mild and of little significance to the patients, especially among those who had not applied for treatment

Thus, apart from the long 10-year intervals Ruelle's type of analysis indicates that his figures refer only to osteoarthritis causing symptoms of such severity that the patients had applied for treatment

If we calculate, on this presupposition, the expected osteoarthritis rate in Helbo's series at the time of follow-up by means of figures from that of Ruelle's groups of diseases in which the primary deformity corresponds to that in Helbo's series, the result ought to be that the calculated

osteoarthritis rate would correspond in all essentials to the *percentage* of osteoarthritis *presented* for treatment in Helbo's material (34 %), not to the higher percentage (62 %) of all cases of clinical osteoarthritis found by him

But which of Ruelle's groups is suited for such a calculation?

Ruelle's *total* material comprises patients with all kinds of *primary deformity* – mild as well as severe, but presumably predominantly severe – following upon congenital *dislocation, subluxation, epiphysiolysis*, and (a few) LCPD.

Helbo's *series*, which consists of "untreated" LCPD cases, is also a predominantly *severely deformed material*

A priori it might be assumed, therefore, that the deformities in Ruelle's total series would correspond in arthritogenic effect quite well to those in Helbo's series (like the deformities in the special groups of patients closest to the middle epiphysiolysis, LCPD, and *subluxation*)

Using the figures from Ruelle's total *material for the* calculation the rate, therefore, ought to correspond quite well to Helbo's percentage of osteoarthritis that had been *presented* for treatment and should preferably be *somewhat higher!*

This proved to be *entirely true* The calculated osteoarthritis rate was 41 %, the actual rate 34 %

Thus, the deformities in Ruelle's total *material (RU I–II)* seem to correspond well to *those* in Helbo's – that is if Ruelle's *values*, as substantiated above, refer to *patients who have* applied for treatment of their osteoarthritic symptoms

The correctness of this supposition is also *indicated by the following There is a* striking difference in the percentage of clinical *osteoarthritis* found at follow up examination of Helbo's series – 62 % – and *at follow* up *examination of Danielsson* & Hernborg's LCPD series – which was only *23 %* *It* is striking because the mean age (and the age distribution at *onset of the* disease) is the same in both series and because the treatment of both series had been of little efficacy – (somewhat *better* in Danielsson & Hernborg's, viz 6 months' *non-weightbearing against* at *most* 3 months' in Helbo's).

On the other hand, the percentage of *radiological* osteoarthritis was approximately the same in both series Danielsson & Hernborg's *50 %* and Helbo's *56 %* This small difference is perhaps explicable by the *somewhat more* effective treatment of Danielsson & Hernborg's *series* – but this explanation can by no means account for the enormous difference between the clinical cases of osteoarthritis in the two very similar *series*

The only conceivable explanation is that Helbo's "clinical osteoarthritis" did not signify the same as Danielsson & Hernborg's, comprising a far larger number of mild cases than Danielsson & Hernborg's

Possibly, their criteria of clinical osteoarthritis do not *differ much in theory*, but in practice they function very differently Indeed it is *(almost)* impossible to set up a definite objective criterion of clinical osteoarthritis

Below, the term criteria refers exclusively to their function in practice

Thus Danielsson & Hernborg's criteria of clinical osteoarthritis appear to be far stricter than Helbo's

But plotting of 3 curves for the development of clinical osteoarthritis in three large series of predominantly *primary* osteoarthritis, reported by Ruelle, Danielsson, and Graber Duvernay, *shows* that these curves practically coincide (Ruelle 1961, *Danielsson* 1964, Graber-Duvernay (quoted by Francon 1956) (Diagram 38))

This can in fact only be interpreted to the effect that the three authors have had the same criterion of "clinical osteoarthritis" – in particular that in *practice* Danielsson's and Ruelle's has been the same

However, the results of the follow up *examination of* secondary osteoarthritis

showed, as already mentioned, that Danielsson's criterion, also used by Danielsson & Hernborg, must be considerably stricter than *Helbo's*

This, then, must apply also to Ruelle's criterion — just what had to be expected, if it is correct that Ruelle's rates, unlike Helbo's, refer exclusively to osteoarthritis of a severity so that the patients soon apply for treatment

The course of the curves confirms that this *is* correct

The similarity of Danielsson's and Ruelle's criteria of clinical osteoarthritis also explains why the calculated percentage in Danielsson & Hernborg's material corresponds to the percentage of *all* clinical cases of osteoarthritis found – 28 %/23 % – and not, as in Helbo's series, to only *a fraction* of them, viz those presented for treatment – 41 %/34 %

The two fractions are equal = 1 2 – which might indicate that Danielsson's criterion of clinical osteoarthritis corresponds quite accurately to what characterizes the cases of osteoarthritis presented for treatment in Helbo's series

These curves are highly informative and afford further support to the other arguments that the percentage of osteoarthritis calculated on the basis of Ruelle's figures refers in all essentials *only to the percentage of osteoarthritis presented for treatment*

Table 8. Statistical calculation

Application of the Fisher Yates test (two-tailed)(Geigy Wissenschaftliche Tabellen 7th Ed p 109) showed that

I The frequency of patients with *normally spherical"* heads differed significantly in the	
Tr series and Wh series as referred	$p < 0.01$
Tr series and BR series as referred	$p < 0.01$
A II groups of the Tr series and Wh series	$p < 0.01$
A II groups of the Tr series and BR series	$p < 0.05$
Boys of the A II groups of the Tr series and of the Wh series	$p < 0.001$
Boys of the A II groups of the Tr series and of the BR series	$p < 0.02$
The frequency of patients with *spherical* heads differed significantly in the	
Boys of the A II groups of the Tr series and Wh series	$p < 0.05$
II The frequency of patients with *spherical* heads did *not* differ significantly in the	
Tr series and Wh series as referred	$p > 0.05$
Tr series and BR series as referred	$p > 0.05$
A II groups of the Tr series and of the Wh series	$p > 0.05$
A II groups of the Tr series and of the BR series	$p > 0.05$
Boys of the A II groups of the Tr series and BR series	$p > 0.05$

Whether the different groups of patients are statistically comparable is discussed in the text

PATIENT LISTS

The patient lists for the traction and bed rest series comprise all patients referred for LCPD to the Seaside Hospital, Refsnæs, during the periods 1958–63 and 1953–57 respectively

All figures on the lists refer to unilateral cases on which the evaluation was based The remainder – the majority bilateral – are only marked Excl (excluded) adding the reason for exclusion

The patients of the wheelchair series are arranged in the same way – only 17 patients from the study period (1957–64 incl) are missing, as they were excluded before J M got the opportunity to see the series Nearly all these cases were bilateral

The number of the patients of the 3 series treated for LCPD is then

	Number of pts.	% of all treated cases
Unilateral cases		
Wheelchair series	114	
Bed rest series	79	
Traction series	113	
Bilateral cases		
Wheelchair series	21	15 6 %
Bed rest series	14	15 1
Traction series	24	17 5

(As to the justification of excluding bilateral cases in the evaluation of the therapeutic results cf Meyer 1966)

Table 31 Number of patients with dysplasia of the capital femoral epiphysis (J.M 1964) *(this number can only be approximate as the limit between dysplasia and typical LCPD is not sharp)*

Wheelchair series	Unilateral dysplasia about 12/144 = 10.5 %
Bed rest series	Unilateral dysplasia. The number is not definitely known as the series was measured before the syndrome dysplasia was described (Meyer 1964) (No >3/79 (3 8 %)).
Traction series	Unilateral dysplasia about 10/113 = 8 8 %, unilateral + bilateral 19/137 = 13 6 %.

Table 30 Development of osteoarthritis in Ruelle s total material of secondary osteoarthritis (pt groups I and II a total of 271 pts)

Among 271 pts with sec osteoarthr who applied for treatment in a rheumat clinic *the symptoms of osteoarthritis started*							Total survey % of all clin cases of osteoarthr developing before the ages stated	
In age group	No of pts	Before age	In No of pts	% of 271 found	Before age	% of 271 calculated (inter polation)	*Age*	% osteo arthritis

CONTENTS

INTRODUCTION

Since the pioneer works of Le Damany (1908) and Ortolani (1937) the modern principles of early diagnosis and treatment of congenital dislocation of the hip (CDH) have been gradually adopted in most countries. The earliest reports of the clinical aspects of the disease are from Russia (Marx 1938), USA (Chapple 1935, Hart 1948), Czechoslovakia (Frejka 1941) and Austria (von Haberler 1944). Investigations on CDH in Sweden have been carried on since 1950 (Palmén 1950, 1957, 1961, 1970, von Rosen 1970, Andrén 1960, Palmén & von Rosen 1975). In Norway important contributions to the subject have been made by Waller & Moe (1954), Njå (1962), Medbøe (1961, 1965) and Bjerkreim (1974). To-day newborn babies in most countries are routinely examined by the classical manoeuvre ("signe de ressault") by which instability of the hip joint can be revealed, and infants with dislocated or dislocatable hips are generally treated with an abduction splint.

The results of the early treatment of unstable hips have been the subject of great interest in medical literature. The most optimistic investigators claim that all or nearly all cases of CDH can be diagnosed in the newborn period and that with correct treatment these children will develop normal hips (Palmén 1961, von Rosen 1970, Fredensborg 1976 a.o.). On the other hand many of the follow up studies include groups of patients in whom apparently correct therapy has failed (Finlay 1967, James et al 1970, Mitchell 1972 a.o.). Finally, a minor group of authors have presented rather discouraging results of early therapy (Weissmann 1966, Ackermann 1974, Bjerkreim 1974). None has as yet given a satisfactory explanation for the divergent therapeutic results of early treatment of unstable hips.

Reviewing the extensive literature on the results of early treatment of CDH I was impressed by the following facts: 1. None of the follow-up studies include control groups of children from the same population matched with the patients for sex and age. 2. Few of the clinical and radiological studies present results which allow definite conclusions of possible "minor" abnormalities of the hip joint. Such abnormalities may pass without obvious symptoms during childhood and adolescence, but may well be the cause of development of arthritic changes of the adult hip. Among such abnormalities increased anteversion of the femoral neck represents a major problem. Despite numerous investigations on that topic, the true nature of the condition is still obscure.

The main aims of the following investigation were:

1. A detailed follow up study of children with unstable hips at birth treated with an abduction splint, in comparison with a control group of presumably healthy children, and a third group of children with unstable hips at birth, but untreated.

2. An evaluation of "minor" pathological findings, with special attention paid to increased anteversion of the femoral neck.

PATIENTS AND METHODS

During the period 1.5.1969–1.5.1971 6509 children (3322 boys and 3187 girls) were born in the two maternity units in Trondheim (E. C. Dahls Stiftelse and the Ob-

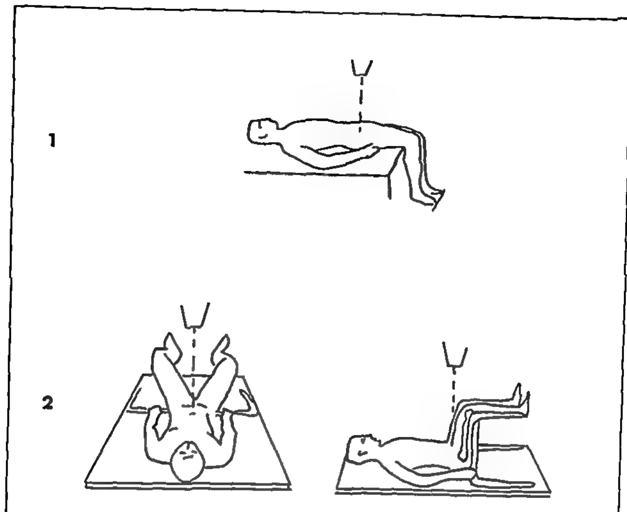

Figure 1 The radiographic examination of the hip joint according to Dunlap and Rippstein 1 An anterior-posterior view of the pelvis 2 The position in Müller's apparatus

stetrical Department of the Regional Hospital of Trondheim) Most of the mothers came from the city of Trondheim whereas a smaller group came from the neighbouring communities The newborns were examined at least twice, the first examination being performed on the first or second day of life and the second generally four to six days after birth About 6000 children were examined by me, the rest by one of the trained consultants of the pediatric department The hips of the newborns were examined according to Palméns and Barlows modification of the Ortolani test (Palmén 1957, Barlow 1962)

In the course of the two years period instability of the hip joint was found in 146 children, 115 girls and 31 boys One child with arthrogryposis was excluded from the material The instability of the hip joint was right-sided only in 38 (26 per cent), left-sided only in 61 (42 per cent) and bilateral in 47 (32 per cent) Breech presentation occurred in 30 children (20 6 per cent)

Table 1 Examination of children with unstable hips at birth and control children with stable hips at the age of four to six years

A	129	unstable hips	Frejkas pillow
B	100	stable hips	none
C	17	unstable hips	none

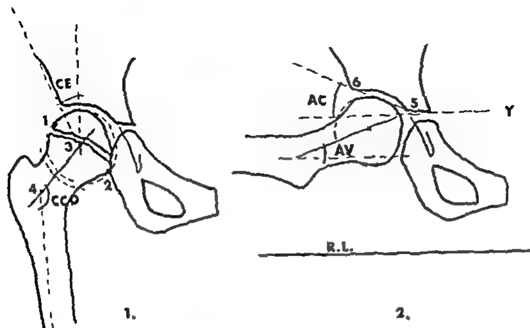

Figure 2 The radiographic measurements of the hip joint 1 The first X ray picture Wibergs angle (CE) and neck shaft angle (CCD) 2 The second X ray picture inclination of the acetabular roof (AC) and torsion (anteversion) of the femoral neck (AV)

All the children with unstable hips were treated in Frejkas cushion splint, usually for three months The patients were checked by me at three months, six months, and fourteen months of age They were radiographed on the last two controls Standardization of the radiological method of these controls was not adequate to make the results suitable for scientific presentation The aim of these controls was primarily to disclose clearly pathological conditions

The control group of children consisted of subjects of the same sex and born chronologically next to the children with unstable hips These children received no treatment

A clinical and radiological follow up study was performed at four to six years of age The follow up study comprised three groups of children (Table 1)

Group A consisted of 123 children (103 girls and 20 boys) with unstable hips at birth, treated with Frejkas pillow Of the originally total number, 146, fifteen patients had moved from the town and were unavailable for the examination

In seven patients of group A (No 20, 54, 61, 78, 93, 99 and 140 the course of the disease was unfavourable, and these patients needed additional treatment at the Orthopedic department with splinting or plaster cast In two of them (No 78 and No 140) a derotational osteotomy was performed

Group B consisted of 100 healthy children (80 girls and 20 boys)

Group C comprised 17 children (12 girls and 5 boys) born at the Maternity Hospital of Haukeland Hospital in Bergen In those infants instability of the hip joint was diagnosed at birth, but all of them had stable joints on the day of discharge from the maternity ward, and no treatment was instituted The diagnosis was made by an experienced pedi-

atrician, and he also followed the children in several controls up to the age of eighteen months

All the clinical examinations of the follow-up study were performed by me The following data were recorded 1 Observations made by the parents such as limping, stumbling, asymmetry of the extremities, in-toeing when walking and subjective symptoms of the child such as fatigue or muscular pain in the extremities 2 Objective examinations shortening and/or atrophy of the lower extremities, Trendelenburg's sign, observation

of the gait, evaluation of the muscular strength and measurements of the range of passive movement. Flexion and abduction were measured in the supine position, extension, internal and external rotation were measured in the prone position. In addition abduction and internal and external rotation were measured in the supine position with hips and knees at right angles. This was mainly performed in order to be able to compare measurements with those of the newborn children who have a marked flexion contracture.

The children were radiographed by specially trained assistants, and I participated in most of the examinations. The rad [illegible] formed. [illegible] tion of [illegible] al 1953, Rippstein 1955). Two exposures were made (Figure 1). An anterior-posterior view of the pelvis and the hips with the patient in the supine position, hips extended, thighs parallel and knees flexed 90° over the edge of the table. The child placed on a simple apparatus constructed by Müller (Muller 1970) which holds the knees and hips flexed at 90° and thighs abducted 20°. The first exposure required 100 mA at 60 kV in 1.2 sec, the second 30 mA at 75 kV in 0.3 sec.

All the measurements of the radiographs (Figure 2) were performed by means of Müllers ischiometer (Müller 1970). On the first x-ray picture I measured the neck-shaft angle (CCD), Wibergs angle (CE) which is the angle between a vertical line through the femoral head and a line from the center of the head to the lateral border of the acetabular roof, and the length and width of the ossified part of the femoral head. The lateral margin of the acetabulum was evaluated and other pathological findings recorded (fragmentation of the epiphysis, ossification defects, subluxations or luxations). On the second picture I measured the anteversion of the femoral neck (AV-angle) and the angle of inclination of the acetabular roof (AC). All measurements were made twice, and the difference between the two values never exceeded 5°, usually it was only 0–2°.

Corrected values of the CCD and AV-angles were computed from the following trigonometric formulas

(I) $\operatorname{tg} AV = \operatorname{tg} AV' \times [\cos(CCD' - 90 - \gamma) - \cos(CCD' - 90)]$

(II) $\cot CCD = \cot CCD' \times \cos AV$

The collected data were processed in a UNIVAC 1108 at the Computing Centre of the University of Trondheim The mean values of groups A, B and C were computed Differences of means were tested by the t-test, and P-values below 0 05 were regarded as statistically significant When indicated, regression curves and confidence limits were computed Correlation coefficient > 0 75 was regarded as positive

RESULTS

1 *The motor development of children with unstable hips at birth*

Of the 146 children with unstable hips at birth 83 were examined at three months of age Results of the examination are shown in Table 2 In nearly all children the range of passive abduction with hips 90° flexed was 80–90°

Ninety-four children were examined at the age of five to ten months (Table 3) At this age the group of children with maximal abduction capacity was reduced to nearly 70 per cent

The results of the clinical examination of 89 children over one year of age are shown in Table 4 27 children were

unstable hips at birth is shown in Table 6 It can be seen that in 67 per cent of the cases retardation of the ossification process appeared on the same side as the instability of the hip joint at birth, whereas in the rest there was no correlation between the retarded ossification and the instability of the hips

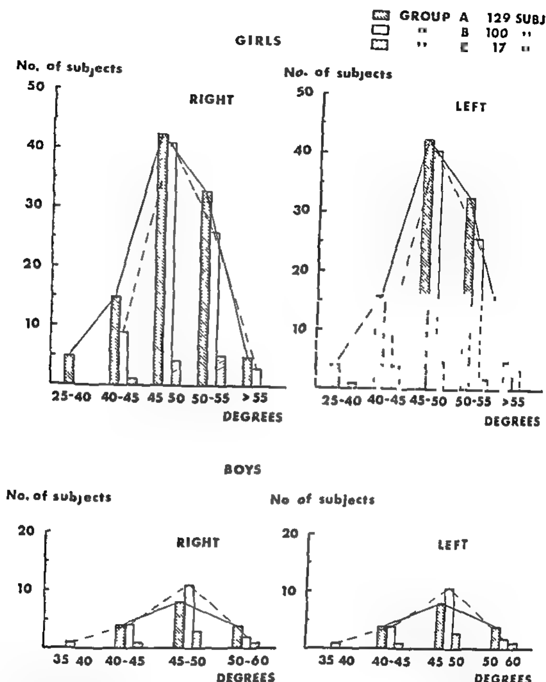

Figure 4 The range of passive abduction with extended hips in 129 children with unstable hips at birth treated with Frejkas pillow 100 healthy children and 17 children with unstable hips at birth untreated

examined at the age of 12 14 months, 46 at 15 17 months and 16 at 18–21 months The maximal abduction capacity was practically unaltered compared with the previous examination

Table 5 shows the development of walking As can be seen nearly 50 per cent of the children started to walk without support between 13 and 15 months

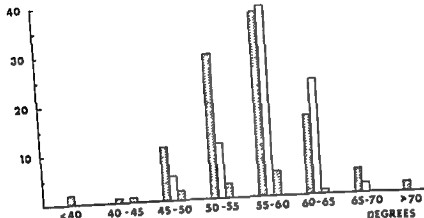
Table 7 shows the frequency of radiological findings described as "dysplasia" by different radiologists



3 *Results of the clinical examination at 4–6 years of age*

The data regarding the further motor development of the children of group A and group B are based on information from the parents (Table 8) It can be seen that the frequency of abnormalities was higher in group A than in group B The most frequent observation in both groups was in-toeing when walking In group A the in-toeing could be seen at clinical examination in 6 children, in group B in two children

Among the patients of group A six presented symptoms of complicating abnormality or disease Four of them (No 31, 71, 777 and 119) are described in detail in "Case Histories" One girl (No 17) had signs of rheumatoid arthritis with a relative shortening of the right lower extremity of 8 mm One boy (No 109) had bilateral pes equinovarus

27 There is no difference between the groups The values for children of group C were not computed as they included some relatively older children

5 *Correlation of the radiological results*

Figure 14 and Figure 15 illustrate the correlation of values of the CE-angle and

igure 17 The correlation of the E angle and AC angle of the eft hip in 103 girls with nstable hips at birth 0 healthy girls and 12 girls with unstable hips at birth untreated

correlation between values of the AV-angle of girls and the age of the subjects In group A the cor coef was 0 07 for the right hip and ■ 08 for the left In group B the corresponding values were 0 41 and 0 20 The small number of values for group C yielded cor coef of — 0 14 and 0 35 for the right and left side respectively

Table 28 shows the correlation between the length and width of the epiphysis and the age of the subjects The girls of both group A and group B showed a definite correlation whereas no correlation was found in boys In group C there was a positive correlation for all groups of values except for the width of the epiphysis of boys

No correlation was found between the values of the CE-angle and CCD-angle and the age of the subjects

As can be seen from the Table 29 there is no relation between the age when the children started to walk without support and the values of the AV-angle Those results are based upon informations from the parents of 72 children of group A

Table 30 shows the average values of the AV-angle of 11 children of group A who showed a gradual increase of passive internal rotation during the first year of life The average value for boys was 37 8° for the right hip and 34 6° for the left hip The corresponding values for girls were 45 8° and 39 5° The latter values are near the upper normal level

In Table 31 is shown the correlation between the height/weight ratio of the children and the values of the AV-, CCD- and CE-angles Individuals with height/weight ratio below the 50th percentile have statistically significantly higher

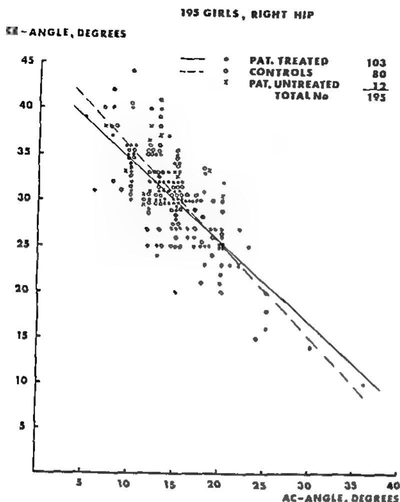

Figure 16 The correlation of the CE-angle and AC-angle of the right hip in 103 girls with unstable hips at birth treated with Frejkas pillow, 80 healthy girls and 12 girls with unstable hips at birth untreated

Figure 16 and Figure 17 show the correlation between values of the CE-angle and the AC-angle of girls in the right hip and the left hip respectively The cor coef of group A was — 0 72 and that of group B — 0 75 The difference between the two groups is without practical importance

Figure 18 shows an attempt to find a possible correlation between values of the CE-angle and AV-angle No correlation could be proved, but the regression lines of values of group A and values of group B were different

No correlation could be found between the retarded ossification of the femoral head and increased anteversion of the femoral neck

No correlation could be found between values of the AV-angle and the CCD-angle (cor coef 0 27).

6 *Correlation of some clinical and radiological findings*

Figure 19 illustrates the correlation between the passive internal rotation movement and the values of the AV-angle The correlation was very poor (cor coef 0 52) For the sake of simplicity only the figures for the left hip of the girls in the prone position are shown, but the same results were obtained for the rest of the material

Figure 20 shows the values of the AV-angle of boys related to the age of the subjects There is no correlation for values in group A (cor coef of the right hip 0 027 and the left hip 0 035) In group B the corresponding figures for the cor coef are — 0 41 and — 0 397, and in group C — 0 61 and — 0 397

Figure 21 and Figure 22 illustrate the

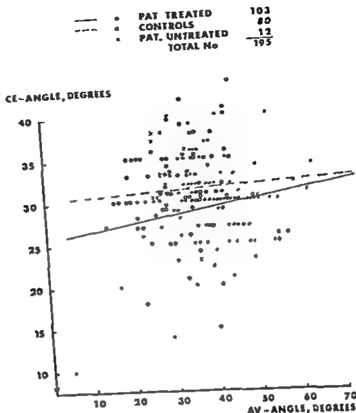

Figure 18 The correlation of the CE angle and AV-angle of the right hip in 103 girls with unstable hips at birth treated with Frejkas pillow, 80 healthy girls and 12 girls with unstable hips at birth untreated

Table 29 The AV angle in relation to the development of walking in children with unstable hips at birth

Age of walking without support in months	AV angle in degrees (left hip)				
	20–29	30–39	40–49	50–59	[illegible]
9–12	6	9	9	3	0
13–15	8	18	4	3	1
16–19	4	2	4	1	0

Conclusion normal clinical and radiological findings

2 *Patient no 1 An 040569 Female*

No cases of CDH in the family Breech presentation The birth induced by oxytocin Positive dislocation test in the left hip on the second day of life Treated with Frejkas cushion splint for three months At that age normal clinical findings

Walked without support 14 months old

Sixteen months of age internal rotation 90°, external rotation 90°, abduction 80° X-ray picture normal

Six years old flexion 135°, extension 20°, abduction 40°, internal rotation 75°, external rotation 10° Hips 90° flexed

Table 28 Length and width of the epiphysis of the femoral head correlated with age in 129 children with unstable hips at birth treated with Frejkas pillow (Group A), 100 healthy children (Group B) and 17 children with unstable hips at birth untreated (Group C)

values of the AV-angle than those with a ratio above the 50th percentile. The values for the CCD- and CE-angles showed no significant difference between the two groups.

CASE HISTORIES

The following case histories illustrate some of the characteristic findings for the different categories of patients.

1. *Patient no 39 Da 101269 Male*

No known cases of CDH in the family. Vertex presentation. Positive dislocation test in the left hip on the first day of life, negative on the fourth day. Frejkas pillow used for three months. At that age normal clinical findings.

Six months old: internal rotation 70°, external rotation 90°, abduction 90°. X-ray: "possibly indistinctly marked lateral margin of the left acetabulum".

Eighteen months: internal rotation 50°, external rotation 80°, abduction 80°. X-ray: normal findings.

Six years of age: flexion 135°, extension 20°, abduction 50°, internal rotation 50°, external rotation 45°. Hips 90° flexed: abduction 55°, internal rotation 50°, external rotation 45°. X-ray: femoral epiphysis 29 × 14 mm, AC-angle 12°, CE-angle 28°, CCD-angle 140°, AV-angle 26° (Figure 23).

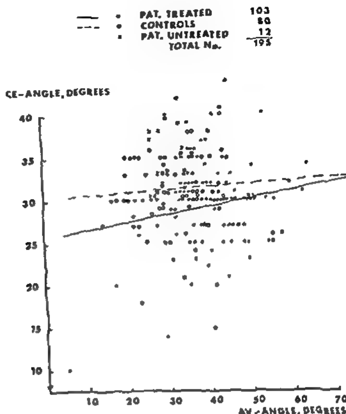

Figure [illegible] The correlation of the CE-angle and AV angle of the right hip in 103 girls with unstable hips at birth treated with Frejkas pillow, 80 healthy girls and 12 girls with unstable hips at birth untreated

Table 29 The AV angle in relation to the development of walking in children with unstable hips at birth

Age of walking without support in months	AV angle in degrees (left hip)				
	20–29	30–39	40–49	50–59	59
9–12	6	9	9	3	0
13–15	8	[illegible]	4	3	1
16–19	4	2	4	1	0

Conclusion normal clinical and radiological findings

2 *Patient no 1 An 010569 Female*

No cases of CDH in the family Breech presentation The birth induced by oxytocin Positive dislocation test in the left hip on the second day of life Treated with Frejkas cushion splint for three months. At that age normal clinical findings

Walked without support 14 months old

Sixteen months of age: internal rotation 90°, external rotation 90°, abduction 80° *X-ray picture normal*

Six years old: flexion 135°, extension 20°, abduction 40°, internal rotation 75°, external rotation 10° Hips 90° flexed

Table 28 Length and width of the epiphysis of the femoral head correlated with age in 129 children with unstable hips at birth treated with Frejkas pillow (Group A), 100 healthy children (Group B) and 17 children with unstable hips at birth untreated (Group C)

values of the AV-angle than those with a ratio above the 50th percentile. The values for the CCD- and CE-angles showed no significant difference between the two groups

CASE HISTORIES

The following case histories illustrate some of the characteristic findings for the different categories of patients

1 *Patient no 39 Da 101269 Male*

No known cases of CDH in the family Vertex presentation Positive dislocation test in the left hip on the first day of life, negative on the fourth day Frejkas pillow used for three months At that age normal clinical findings

Six months old internal rotation 70°, external rotation 90°, abduction 90° X-ray "possibly indistinctly marked lateral margin of the left acetabulum"

Eighteen months internal rotation 50°, external rotation 80°, abduction 80 X-ray normal findings

Six years of age flexion 135°, extension 20°, abduction 50°, internal rotation 50°, external rotation 15° Hips 90° flexed abduction 55°, internal rotation 50°, external rotation 15° X-ray femoral epiphysis 29 × 14 mm, AC-angle 12 CE-angle 28°, CCD-angle 140°, AV-angle 26° (Figure 23)

Figure 20 The values of the AV angle related to the age of 26 boys with unstable hips at birth treated with Frejkas pillow 20 healthy boys and 5 boys with unstable hips at birth untreated

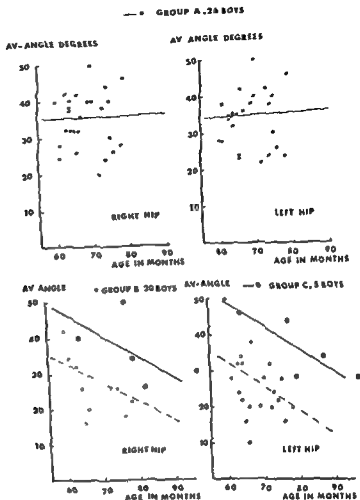

Table 31 The relation between the height/weight ratio of 125 children and the AV, CCD- and CE-angle

Height Weight ratio	AV angle		CCD angle		CE-angle	
	Mean	S D	Mean	S D	Mean	S D
< 50 percentiles	37 20	9 74	135 47	6 43	30.32	4.82
> 50 percentiles	32 68	8 56	135 97	5 80	30 44	5 43

Conclusion increased range of passive internal rotation Increased anteversion of the femoral neck

3 *Patient no 138 Hu 050170 Male*

No cases of CDH in the family Vertex presentation Birth weight 2830 g Dysmature appearance Positive dislocation test in both hips on the second day, negative on the eight day Treated with Frejkas pillow

Three months old internal rotation 60°, external rotation 80°, abduction right side 80°, left side 60° Treatment with Frejkas pillow continued to five months

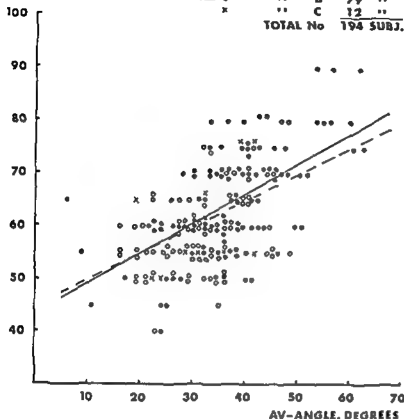

Figure 19 The correlation between the passive internal rotation and the AV angle of the left hip in 103 girls with unstable hips at birth treated with Frejkas pillow, 79 healthy girls and 12 girls with unstable hips at birth untreated

Table 30 The AV-angle at four to six years in relation to the increasing passive internal rotation during infancy Observations in 11 children with unstable hips at birth

No	Sex	AV angle in degrees Right hip	Mean	Left hip	Mean
1	M	40		40	
2	M	43		35	
3	M	41	37 8	39	34 6
4	M	39	(boys)	33	(boys)
5	M	26		26	
6	F	44		37	
7	F	36		36	
8	F	50	45 8	50	39 5
9	F	45	(girls)	40	(girls)
10	F	39		32	
11	F	43		42	

internal rotation 75°, external rotation 10°, abduction 50° X-ray femoral epiphysis 32 × 12 mm, AC-angle 10°, CE-angle 34°, CCD-angle right side 138°, left side 140°, AV-angle right side 63°, left side 62° (Figure 24)

Conclusion asymmetrical development of the hip joint both on clinical and radiological examination

5 *Patient no 119 Vau 140970 Female*

No cases of CDH in the family Breech presentation forceps delivery Birth weight 2620 g *Dysmature appearance* Positive dislocation test in the right hip on the first day of life, negative on the third day Treated with Frejkas pillow for three months Did not come to follow-up afterwards

Five years old

Position		Movement	right hip	left hip
supine	hips 0°	flexion	120°	120°
		abduction	25°	35°
		adduction	20°	20°
	hips 90° flexed	abduction	15°	30°
		internal rotation	65°	50°
		external rotation	45°	45°
prone		extension	25°	25°
		internal rotation	70°	70°
		external rotation	20°	30°
X ray findings (Figure 27)		femoral epiphysis	24 × 11 mm	24 × 11 mm
		AC angle	15°	10°
		CE-angle	30°	35°
		CCD angle	143°	141°
		AV angle	43°	44°

Conclusion restricted movements and increased internal rotation of the right hip Increased anteversion of the right femoral neck

6 *Patient no 31 So 281069 Female*

No hip anomalies in the family Vertex presentation birth induced by oxytocin A positive dislocation test on the second day of life negative on the fourth day Treated with Frejkas pillow for three months at that stage normal clinical findings

Eight months internal rotation 80 external rotation 90 abduction 90° Walked without support 15 months old

Seventeen months internal rotation 75 external rotation 90 abduction 80° Shortly afterwards the mother observed that the child did not move her left arm normally and slight spasticity of the left leg was noticed Treated with physiotherapy

Five and a half years old flexion 115° extension 20°, abduction 50°, adduction 15° internal rotation 60°, external rotation 50° Hips 90° flexed abduction 50°, internal rotation 35°, external rotation 70°

X ray findings (Figure 28)

	right hip	*left hip*
femoral epiphysis	32 × 16 mm	32 × 14 mm
AC-angle	15°	21°
CE angle	20°	20°
CCD angle	140°	137°
AV angle	17°	23°

Conclusion cerebral palsy Left sided hemiparesis Relatively increased *anteversion of the left femoral neck*

7 *Patient no 71 Ne 241270 Female*

No hip abnormalities in the *family Breech* presentation, forceps delivery *Erythroblastosis* foetalis Fourteen hours

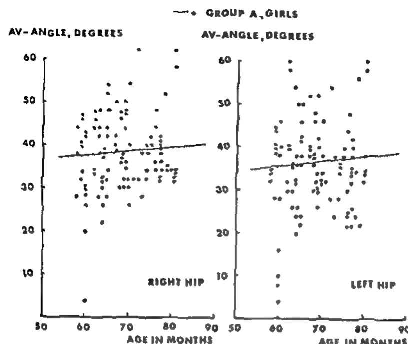

Figure 24 The values of the AV-angle related to the age of 103 girls with unstable hips at birth treated with Frejkas pillow

Nine months internal rotation 40°, external rotation 80°, abduction 60° X-ray negative

Five years old flexion 135°, extension 20°, abduction 40°, internal rotation 60°, external rotation 45° Hips 90° flexed internal and external rotation 60°, abduction 45° X-ray femoral epiphysis right side 26 × 11 mm, left side 24 × 12 mm, AC-angle 17°, CE-angle right side 24°, left side 28°, CCD-angle right side 134°, left side 138°, AV-angle right side 25°, left side 38° (Figure 25)

Conclusion asymmetrical development of the hip joint Relative increase of the anteversion of the femoral neck of the left side Normal clinical findings

4 *Patient no 77 No 230271 Female*

No known hip anomalies in the family Vertex presentation Positive dislocation test in the left hip on the first day of life, negative on the fourth day Treated with Frejkas pillow for three months, did not come to follow-up afterwards

Five years old

Position		Movement	right hip	left hip
supine	hips 0°	flexion	135°	135°
		abduction	45°	45°
		adduction	20°	20°

Figure 29. Radiological examination of a five years old girl with a positive dislocation test in the right hip at birth. R: Cerebral palsy. General spasticity. Bilateral increase of the anteversion of the femoral neck. AV angle: right 67°, left 61°.

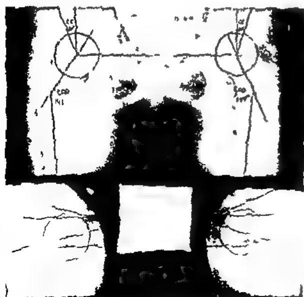

Figure 28. Radiological examination of a five years old girl with a positive dislocation test in both hips at birth. R: Cerebral palsy. Hemiparesis sin. Asymmetrical development of the hips. AV angle on the right side 17°, on the left side 23°.

Figure 30. Radiological examination of a six years old girl with a positive dislocation test in the right hip at birth, left untreated. R: Normal findings.

Clinical and radiological controls at two six and eighteen months of age revealed nothing pathological. Walked without support 11 months old.

Six years old flexion 125°, extension 20°, abduction 50°, adduction 20°, internal rotation 50°, external rotation 35°. Hips 90° flexed abduction 60°, internal rotation 55°, external rotation 60°. *X-ray femoral epiphysis 25 × 12 mm* AC-angle 20°. CE-angle right side 30°, left side 34°, CCD angle right side 135°, left side 130°. AV angle right side 26°, left side 22° (Figure 30).

Conclusion clinically and radiologically normal findings.

DISCUSSION

1 *Patients and methods*

The Trondheim area offers good conditions for the investigation of the problems of congenital dislocation of the hip. All children are delivered in two maternity clinics and examination of the newborn are performed by few experienced pediatricians. All cases of the late diagnosis dislocation of the hip are referred to the orthopaedic department of the Regional Hospital.

The frequency of unstable hips in the present material was 22.4 ‰. Apart from data reported by Harlem (1961) and Ramstad (1964) the incidence in Trondheim is the highest reported in Norway (Kiss 1961, Medbo 1961, Torp 1961, Nja 1962, Bjerkreim 1974, Hoyer 1975). Among the widely differing results published from different countries it is not difficult to find incidence of unstable hips similar to ours (James & Sevastiкoglou 1970, Fredensborg 1976). Apart from the fact that incidence of unstable hips of the newborn in Trondheim has shown a tendency to decrease during recent years (from 20 to 15 ‰) the findings have been remarkably stable and there is reason to believe that the figure of 22 ‰ represents the true incidence of unstable hips of newborn in the region.

In the examination of the newborn I used both the abduction test and the subluxation provocation test (Palmen 1957, Barlow 1962). I did not try to classify unstable hips into dislocated and dislocatable (Finlay et al 1967, Barlow 1962, Rosenblum et al 1972, Siffert et al 1972, Komprda 1974), as I had a strong impression that it depended largely on the position of the legs, whether I found the hips in or out of joint at the time of examination. Atypical clicks of the hip joint were not recorded as they seem to be without clinical significance (Sommer 1971).

The sex distribution, side affected and the incidence of breech presentation are in accordance with the results of other neonatal series (Palmen 1961, Hirsch & Scheller 1970, Lauritzen 1971, Huttova et al 1972, Ritter 1973, Bjerkreim 1974, Ackermann et al 1974, Artz et al 1975).

One of the main problems of the present investigation was to find a suitable group of control children. Being aware of the sex and racial variations of the incidence of CDH (Getz 1955), geographical distribution (Bjerkreim 1974), seasonal fluctuations (Record & Edwards 1958, Nagura 1955, Pap 1956, Uibe 1959, Chen et al 1970, Andren & Palmen 1963) and possible other factors in the pathogenesis of neonatal CDH, I tried to find a control group within the population of Trondheim.

I sent an inquiry to all the parents of the children of the same sex born chronologically next to the children with unstable hips. All those children had been examined by me at birth. They had stable hips and received no treatment. One can not be sure that the group represents completely "normal" material. In a few cases the parents reported of hip abnormalities in the family. The control group differed from the patient group with respect to birth order of the child in the family. In

DISCUSSION

1 *Patients and methods*

The Trondheim area offers good conditions for the investigation of the problems of congenital dislocation of the hip All children are delivered in two maternity clinics, and examination of the newborn are performed by few, experienced pediatricians All cases of the "late diagnosis" dislocation of the hip are referred to the orthopaedic department of the Regional Hospital

The frequency of unstable hips in the present material was 22.4 °/₀₀ Apart from data reported by Harlem (1961) and Ramstad (1964) the incidence in Trondheim is the highest reported in Norway (Håss 1961, Medbø 1961, Torp 1961, Nja 1962, Bjerkreim 1974, Hoyer 1975) Among the widely differing results published from different countries it is not difficult to find incidence of unstable hips similar to ours (James & Sevastikoglou 1970, Fredensborg 1976) Apart from the fact that incidence of unstable hips of the newborn in Trondheim has shown a tendency to decrease during recent years (from 20 to 15 °/₀₀) the findings have been remarkably stable and there is reason to believe that the figure of 22 °/₀₀ represents the true incidence of unstable hips of newborn in the region

In the examination of the newborn I used both the abduction test and the subluxation provocation test (Palmen 1957, Barlow 1962) I did not try to classify unstable hips into "dislocated" and "dislocatable" (Finlay et al 1967, Barlow 1962, Rosenblum et al 1972, Siffert et al 1972, Komprda 1974), as I had a strong impression that it depended largely on the position of the legs, whether I found the hips in or out of joint at the time of examination "Atypical clicks" of the hip joint were not recorded as they seem to be without clinical significance (Sommer 1971)

The sex distribution, side affected, and the incidence of breech presentation are in accordance with the results of other neonatal series (Palmen 1961, Hirsch & Scheller 1970, Lauritzen 1971, Huttova et al 1972, Ritter 1973, Bjerkreim 1974, Ackermann et al 1974, Artz et al 1975)

One of the main problems of the present investigation was to find a suitable group of control children Being aware of the sex and racial variations of the incidence of CDH (Getz 1955), geographical distribution (Bjerkreim 1974), seasonal fluctuations (Record & Edwards 1958, Nagura 1955, Pap 1956, Uibe 1959 Chen et al 1970, Andren & Palmen 1963) and possible other factors in the pathogenesis of neonatal CDH I tried to find a control group within the population of Trondheim

I sent an inquiry to all the parents of the children of the same sex born chronologically next to the children with unstable hips All those children had been examined by me at birth They had stable hips and received no treatment One can not be sure that the group represents completely normal material In a few cases the parents reported of hip abnormalities in the family The control group differed from the patient group with respect to birth order of the child in the family In

the patient group (A) 75 children (58 per cent) were first-born, whereas in the control group (B) 39 children (39 per cent) wer first-born The control group and the patient group were not matched for possible differences in social class distribution One boy originally in the control group revealed serious abnormalities of the hip joint, probably due to Calve-Legg-Perthes disease This child was excluded from the series Another girl with a probable developmental anomaly of the lower extremities was also excluded

Nearly 70 per cent of the parents of the control children responded to the inquiry Among the remainder the majority had moved from the town and some refused the examination One cannot exclude the possibility that among the 30 per cent children not examined there might be so many pathological findings that the differences between groups A and B might be minimized It is not very likely, however, as parents generally are aware of even small abnormalities of their childrens development In addition, most of the children are regularly examined at welfare clinics, and examination of the hip is included in the routine examination at most centres

Fifteen patients with unstable hips at birth were not examined because they had moved from the town It is impossible to say how additional results from examination of this group might have influenced the final results However, with the present results in view, one can not exclude the possibility that differences between group A and B might be even greater

Of the 146 children with unstable hips at birth eleven received prolonged treatment wiht a plaster cast Seven of them were examined by me As one of the purposes of the present investigation was to study the effect of various factors upon the development of the hip joint, it seemed correct to include these patients in the series In the final analyses mean values with and without these patients were compared, and there was no differences of the results

The follow-up study was performed at four to six years of age This age group was considered suitable for investigation on the following grounds 1 Most children at this age cooperate fairly well and thus permit detailed measurements at both the clinical and radiological examination 2 The development of the hip joint has progressed to such a degree that comparison between different groups of children is possible 3 Practical therapeutic problems often arise in the preschool period, so it might be desirable to complete treatment (especially surgical procedures) before the school age

Before embarking on a radiological examination of the children of the control group it was necessary to evaluate the risks of x-ray studies on healthy individuals (Grossmann 1969, Devik 1971, Erik 1972, Schmidt 1974) Having reviewed the relevant data on the method used in the present investigation, I could not find any contraindications to the examination

The radiographic method of Dunlap (Dunlap et al 1953) modified by Rippstein (1955) has the advantage that only two exposures are necessary The described method has been tested by several investigators (Rippstein 1955, Gross 1972), and the conclusion is that it is sufficiently accurate for scientific purposes

The formula used for the correction of the projected values of the CCD-angle and AV-angle has been the subject of much discussion Obviously the formula given by Muller (1970) is incorrect (Sudman 1976, Rusten 1976), and the formula used in the present study gives correct values Elsasser (1973) holds that the formula is not precise enough for high values of the AV- and CCD-angles, and that the results may vary by as much as 5 degrees He

uses somewhat different projections and his definition of the AV-angle differs from that used in the present study (Gibson 1967, Muller 1970)

The vast literature on the radiological descriptions of the hip gives a strong impression that many variations of both normal and pathological appearances of the joint still remain unexplained Thus, there is no unanimous definition of the concept "dysplasia"

Various descriptions of the acetabulum include the sloping of the acetabular roof (Hilgenreiner 1925, Idelberger & Frank 1952, Caffey et al 1956, Root 1967, Kalenos 1970, Busse et al 1972), areas of sclerosis (Garavaglia 1970) and the thickness of the bottom of the acetabulum (Schindlmaisser & Kotz 1972) Different *measurements* have led to a number of concepts, such as the "Z-line' (Zsernaviczky 1974), "acetabular head-quotient' (Sun Do Hong 1969), "Zentrierungs defect' (Hoffmann-Daimler 1974), "Wibergs angle' (Wiberg 1939) Fellander et al (1970) points out that it is important to distinguish between late ossification of the acetabular roof with a small or absent lateral margin of the roof and ossification defects as signs of real dysplasia Keller (1975) lists the following important radiological signs of real dysplasia "wedge segments delayed ossification of the acetabular roof, taillification" of the acetabular edge double contour of the acetabulum subchondral sclerosis and steep acetabular roof Among the non-osseous signs' Garavaglia (1970) describes the "arcuate line and the "triangular area" as early signs of dysplasia The upper end of the femur has been described by Hadziselimovic & Secerov (1968) and Skrypczak (1971) among others

Many of the radiological findings can only be demonstrated on specially exposed films and some of the results are difficult to interpret I found the measurements of the present study relatively simple and the results of the measurements suitable for statistical analysis

2 *Results*

The study of children with unstable hips at birth has shown several deviations from the normal motor development During infancy the following trends were noticed

At three months of age practically all children had an abduction angle of 80–90 degrees *The frequency* of maximal abduction was reduced to 69 per cent during the *second half* year of life, and remained practically unaltered thereafter

A small group of children (11 patients) showed a gradual increase of passive internal rotation *from* 40–50 *degrees* to 80 90 degrees, whereas the remainder showed either unaltered or reduced capacity for internal rotation

The number of children with external rotation of 80 90 degrees increased from 30 1 per cent at the age of three months to 93 6 per cent during the second half year of life and then decreased to 69 1 per cent after one year of age

On the basis of investigations made by Harris et al (1960), Haas et al (1973) and Coon et al (1975) the normal internal rotation of the hip is $62 \pm 12\,9$ degrees at birth, $26 \pm 3\,4$ degrees at three months and $21 \pm 4\,3$ degrees at six months The external rotation is $89\,1 \pm 14\,3$ degrees at birth, $45 \pm 4\,5$ degrees at three months and $46 \pm 4\,8$ degrees at six months The normal abduction seems to be 80 90 degrees in the newborn and 60 70 degrees at the age of 1 9 months

As will be discussed later one cannot exclude the possibility that the deviating motor development of children with unstable hips at birth has important influence on the development of the hip joint

It is noteworthy that minor abnormalities of the function of the lower extrem-

hies (in-toeing when walking, stumbling and complaints of fatigue) appeared more frequently in the patient group than in the control group

On the basis of the present investigation the following values seem to represent useful guidelines for evaluation of mobility at the age of four to six years flexion 130 ± 15 degrees, extension 20 ± 5 degrees, abduction 45 ± 10 degrees, adduction 25 ± 5 degrees, internal rotation in boys 50 ± 15 degrees and in girls 55 ± 15 degrees, external rotation 55 ± 10 degrees

Clinical examination at the age of four to six years showed several definite differences between the groups A and B. The girls of group A showed on average a pronounced increase of internal rotation and a decrease of external rotation of the hip as compared with girls of group B In conjunction with the radiological findings this is an expression of the increased anteversion of the femoral neck However, the poor correlation between the clinical and radiological findings (Figure 19) would indicate great caution in the evaluation of increased anteversion of the femoral neck on the basis of clinical examinations only

The boys of group A had on average an increased range of passive abduction movement compared with the boys of group B No satisfactory explanation for this tendency could be found In view of the fact that the boys of group A had a decreased range of external rotation, but the same range of internal rotation as boys of group B, it is unlikely that the increased abduction ability should depend on increased laxity of the joint Moreover, one would have expected to find the same tendency in the group of girls

It may be justified to conclude that on average *about 20 per cent of the girls and 10 per cent of the boys of group A showed abnormal function of the hip joint*

The results of the present study seem to indicate that the following values might be used as practical guidelines for the evaluation of x-ray pictures of five to six years old children· AC-angle 14 ± 5 degrees, CE-angle 31 ± 10 degrees, CCD-angle 135 ± 12 degrees, AV-angle in boys 28 ± 18 degrees, in girls 32 ± 16 degrees In the absence of comparable studies one cannot be sure that these values apply to other populations

There are few reports of the normal values of the AC-angle and CE-angle at the age of four to six years Meyer & Schreiber (1964) give values similar to those of the present study, whereas Tonnis & Brunken (1968), Tonnis (1969) and Tonnis & Trede (1970) give somewhat higher values The CE-values of Wiberg (1939) and Severin (1941) are similar to ours

The close correlation between values of the AC-angle and the CE-angle demonstrated in the present study would indicate that it is sufficient to measure only one of the parameters, preferably the CE-angle which is easier to mate

The results of the radiological study would indicate that *nearly 30 per cent of the girls and 10 per cent of the boys of group A present clearly pathological values of the angles measured* (2 S D or above the mean values)

The results of the present investigation contrast with the normal or nearly normal results of most of the previously reported follow-up investigations (Medbo 1961, Palmen 1961, Barlow 1962, Gregersen 1969, von Rosen 1970, James & Sevastikoglou 1970, Creze 1970, Pešek & Ambler 1972, Fredensborg 1976)

Bjerkreim has stressed the important fact that even in children where the clinical course has apparently been satisfactory one may find deviation from normal clinical and radiological findings (Bjerkreim 1974) In his large series 24 1 per cent of the children treated with an abduction splint presented abnormal signs Of those, 12 per cent had in-

creased anteversion of the femoral neck and 12.4 per cent signs of "dysplasia". As Bjerkreim had no control group and did not examine systematically all children treated, some have questioned the reliability of his results (Fredensborg 1976). The results of the present investigation are in agreement with Bjerkreim's findings, the frequency of increased anteversion of the femoral neck being even higher.

The variable results of the different follow-up studies published may be due to one or several of the following factors:

1. *Different* definitions of the concepts "dysplasia", "preluxation", "instability of the hip", "anteversion of the femoral neck" a.o. (Finlay 1967, Komprda 1974).

2. Lack of standardised diagnostic procedures. The diagnosis of instability of the hip in the newborn period is to some extent subjective. Diagnosis may be missed for such reasons as inexperience, difficult examination (crying child, large baby), dislocated irreducible hips or hips with the potential tendency to dislocate later (Ramstad 1964, Sommer 1971, Uher 1972, Mitchell 1972, Moore 1972). On routine clinical examination of older children minor deviations from the normal may easily be missed. Lack of standardised radiological examinations and "normal" values of different age groups make it difficult to compare results from different departments.

3. Congenital *dislocation* of the hip probably comprises different etiological and pathogenetical entities (Carter & Wilkinson 1964, Wynne-Davies 1970, Wilkinson 1972, Stohr 1972). The genetic background may vary for different populations. The classification of neonatal CDH and late diagnosis CDH which seems widely accepted today may be rather arbitrary. The late diagnosis CDH includes at least three *categories of* children: a) those who are insufficiently or not examined at birth, b) newborn with stable hips with a potential to dislocate later and c) dislocated, irreducible hips. Some investigators would also include patients with unstable hips at birth who are inadequately or not treated.

Apart from the fact that instability of the hip joint at birth may lead in a small proportion of children to luxation, subluxation or dysplasia at a later stage, the true connection between the instability of the hip and late pathological states is unclear.

4. Different long-term results of early treatment of unstable hips may depend on different therapeutic regimes (Allen 1962, Fellander et al. 1970, Lauritzen 1971, Emneus 1971, Ilfeld et al. 1972).

3. *The anteversion of the femoral neck*

Family studies of the structure of the hip do not permit any conclusions concerning a possible genetic influence upon the anteversion of the femoral neck (Carter & Williams 1964, Rott 1968, Wynne-Davies 1970, Czeizel et al. 1975). Getz (1955) found an increased anteversion of the femoral neck in adult Lapps, but this may be due to environmental influence (Bjerkreim 1974). His values for children of 20.9 ± 10.8 degrees are not matched with control subjects.

The embryonal development of the hip joint has been studied by Watanabe (1974). He found great individual variations of the AV angle (– 30 to 40 degrees). In contrast to the other structural characteristics of the hip (neck shaft angle, depth of the acetabulum and the inclination of the acetabular roof), the AV angle was independent of the age of the foetus. Neither could he find any correlation between the AV angle and the "dysplastic" hip joint which was demonstrated in 9.1 per cent of the cases.

Wilkinson (1963) states that different types of breech malposition may lead to different development of the shape of the femur. The more common lateral rotation breech malposition with flexion of the knees produces femoral retroversion

ities (in-toeing when walking, stumbling and complaints of fatigue) appeared more frequently in the patient group than in the control group

On the basis of the present investigation the following values seem to represent useful guidelines for evaluation of mobility at the age of four to six years *flexion* 130 ± 15 degrees, extension 20 ± 5 degrees, abduction 45 ± 10 degrees, adduction 25 ± 5 degrees, internal rotation in boys 50 ± 15 degrees and in girls 55 ± 15 degrees, external rotation 55 ± 10 degrees

Clinical examination at the age of four to six years showed several definite differences between the groups A and B The girls of group A showed on average a pronounced increase of internal rotation and a decrease of external rotation of the hip as compared with girls of group B In conjunction with the radiological findings this is an expression of the increased anteversion of the femoral neck However, the poor correlation between the clinical and radiological findings (Figure 19) would indicate great caution in the evaluation of increased anteversion of the femoral neck on the basis of clinical examinations only

The boys of group A had on average an increased range of passive abduction movement compared with the boys of group B No satisfactory explanation for this tendency could be found In view of the fact that the boys of group A had a decreased range of external rotation, but the same range of internal rotation as boys of group B, it is unlikely that the increased abduction ability should depend on increased laxity of the joint Moreover, one would have expected to find the same tendency in the group of girls

It may be justified to conclude that on average *about 20 per cent of the girls and 10 per cent of the boys of group A showed abnormal function of the hip joint*

The results of the present study seem to indicate that the following values might be used as practical guidelines for the evaluation of x-ray pictures of five to six years old children AC-angle 14 ± 8 degrees, CE-angle 31 ± 10 degrees, CCD-angle 135 ± 12 degrees, AV-angle in boys 28 ± 18 degrees, in girls 32 ± 16 degrees In the absence of comparable studies one cannot be sure that these values apply to other populations

There are few reports of the normal values of the AC-angle and CE-angle at the age of four to six years Meyer & Schreiber (1964) give values similar to those of the present study, whereas Tonnis & Brunken (1968), Tonnis (1969) and Tonnis & Trede (1970) give somewhat higher values The CE-values of Wiberg (1939) and Severin (1941) are similar to ours

The close correlation between values of the AC-angle and the CE-angle demonstrated in the present study would indicate that it is sufficient to measure only one of the parameters, preferably the CE-angle which is easier to mate

The results of the radiological study would indicate that *nearly 30 per cent of the girls and 10 per cent of the boys of group A present clearly pathological values of the angles measured* (2 S D or above the mean values)

The results of the present investigation contrast with the normal or nearly normal results of most of the previously reported follow-up investigations (Medbo 1961, Palmen 1961, Barlow 1962, Gregersen 1969, von Rosen 1970, James & Sevastikoglou 1970, Creze 1970, Pešek & Ambler 1972, Fredensborg 1976)

Bjerkreim has stressed the important fact that even in children where the clinical course has apparently been satisfactory one may find deviation from normal clinical and radiological findings (Bjerkreim 1974) In his large series 24 4 per cent of the children treated with an abduction splint presented abnormal signs Of those, 12 per cent had in-

creased anteversion of the femoral neck and 12.4 per cent signs of dysplasia. As Bjerkreim had no control group and did not examine systematically all children treated, some have questioned the reliability of his results (Fredensborg 1976). The results of the present investigation are in agreement with Bjerkreims findings, the frequency of increased anteversion of the femoral neck being even higher.

The variable results of the different follow up studies published may be due to one or several of the following factors:

1. Different definitions of the concepts "dysplasia", "preluxation", "instability of the hip", "anteversion of the femoral neck", a.s.o. (Finlay 1967, Komprda 1974).

2. Lack of standardised diagnostic procedures. The diagnosis of instability of the hip in the newborn period is to some extent subjective. Diagnosis may be missed for such reasons as inexperience, difficult examination (crying child, large baby), dislocated irreducible hips or hips with the potential tendency to dislocate later (Ramstad 1964, Sommer 1971, Uher 1972, Mitchell 1972, Moore 1972). On routine clinical examination of older children minor deviations from the normal may easily be missed. Lack of standardised radiological examinations and "normal" values of different age groups make it difficult to compare results from different departments.

3. "Congenital dislocation of the hip" probably comprises different etiological and pathogenetical entities (Carter & Wilkinson 1964, Wynne-Davies 1970, Wilkinson 1972, Stohr 1972). The genetic background may vary for different populations. The classification of neonatal CDH and "late-diagnosis CDH", which seems widely accepted to-day, may be rather arbitrary. The "late diagnosis CDH" includes at least three categories of children: a) those who are insufficiently or not examined at birth, b) newborn with stable hips with a potential to dislocate later and c) dislocated irreducible hips. Some investigators would also include patients with unstable hips at birth who are inadequately or not treated.

Apart from the fact that instability of the hip joint at birth may lead in a small proportion of children to luxation, subluxation or dysplasia at a later stage, the true connection between the instability of the hip and late pathological states is unclear.

4. Different long term results of early treatment of unstable hips may depend on different therapeutic regimes (Allen 1962, Fellander et al. 1970, Lauritzen 1971, Fmneus 1971, Ilfeld et al. 1972).

3. *The anteversion of the femoral neck*

Family studies of the structure of the hip do not permit any conclusions concerning a possible genetic influence upon the anteversion of the femoral neck (Carter & Williams 1964, Rott 1968, Wynne-Davies 1970, Czeizel et al. 1975). Getz (1955) found an increased anteversion of the femoral neck in adult Lapps, but this may be due to environmental influence (Bjerkreim 1974). His values for children of 20.5 ± 10.8 degrees are not matched with control subjects.

The embryonal development of the hip joint has been studied by Watanabe (1974). He found great individual variations of the AV angle (—30 to 40 degrees). In contrast to the other structural characteristics of the hip (neck shaft angle, depth of the acetabulum and the inclination of the acetabular roof) the AV angle was independent of the age of the foetus. Neither could he find any correlation between the AV angle and the "dysplastic" hip joint which was demonstrated in 9.1 per cent of the cases.

Wilkinson (1963) states that different types of breech malposition may lead to different development of the shape of the femur. The more common lateral rotation breech malposition with flexion of the knees produces femoral retroversion

whereas the medial rotation breech posture leads to femoral anteversion

In the postnatal development of the hip joint both age-dependent, sexual and individual variations are well documented The average values of the AV-angle of infants are reported to be 30–40 degrees, and there seems to be a steady decrease to values of 5–10 degrees in the adult (Dunlap et al 1953, Shands & Steele 1958, Manlot et al 1964, Temturier & Dechembre 1968, Fabry 1973). This age-dependent decrease of values is also observed in children with an initially pathological increased anteversion (Gibson 1967, Schwarzenbach 1971) Heinrich et al (1968) found a temporary increase of the femoral neck anteversion from 30–40 degrees at birth to 40–50 degrees at the age of four years, and a decrease thereafter In the present study the age difference between subjects was relatively small, and the age-dependent tendency could not be convincingly demonstrated This justifies the computing of the total number of values of groups A, B and C

The normal values given for the AV-angle of children at the age of four to six years differ considerably in the available reports The following figures illustrate some of the diverging results 20 degrees (Shands & Steele 1958), 22 degrees (Dunlap et al 1953), 26 7±7 4 degrees (Fabry 1973), 20–30 degrees (Rogers 1934), 23–40 degrees (Temturier 1968), 30 50 degrees (Heinrich et al 1968) Different techniques of examination may explain the different results, but the influence of different populations cannot be excluded The present findings of 27 5 ± 8 degrees in boys and 31 5 ± 8 degrees in girls are practically the same as those of Fabry However, he gives no difference between boys and girls

The present study also demonstrated a correlation between the anteversion of the femoral neck and the build of the child Slender children on average have higher values of the AV-angle compared with those of the more "athletic" type This suggests a possible influence of the muscular activity upon the degree of anteversion.

If the muscular influence upon the bony structures is exerted through balanced muscle tone, one would not expect to find any correlation between the age of walking start and the values of the AV-angle. This assumption was in accordance with the findings of the present study.

As early as 1934 Rogers pointed out that various pathological conditions may cause an increase of the anteversion of the femoral neck Among the conditions listed in his report are: fractures, poliomyelitis, osteomyelitis, and congenital dislocation of the hip

Cahuzac et al (1974) have shown that cerebral palsy has a valgelizing effect on the femur, and demonstrated that inactivity accentuated this effect

Fabry et al (1973) demonstrated increased anteversion of the femoral neck in coxa plana

In the present investigation the highest values for the AV-angles (right 67 degrees, left 61 degrees) were found in a girl with cerebral palsy (Pat no 71) Another girl (no 31) with a hemiparesis showed increased anteversion of the femoral neck on the same side A girl with polyarthritis (no 17) showed high values of the AV-angle (43 degrees)

The association between increased anteversion of the femoral neck and congenital dislocation of the hip has been accepted for several years (Alvik 1962, Gibson 1967, Dabadie 1971, Fabry 1973, Bjerkreim 1974) In most cases of CDH increased anteversion could also be demonstrated on the "unaffected" side (Dunlap et al 1953, Shands & Steele 1958, Fabry 1973) The published data seldom give information about the type of congenital dislocation treated, but probably most of the patients are of the so-called late-diagnosis type treated with a plaster

ca l or by operation It has not been possible to find any controlled examination of the AV angle of children with unstable hips at birth The present investigation demonstrates that the problem of increased anteversion of the femoral neck exists also in this group of patients

The development of the hip in children of the present series who received prolonged treatment is of special interest Of the eleven patients treated with plaster cast four eventually underwent derotational osteotomy Even if those children were not examined by the same method as used in the present study one must assume that they had considerably increased anteversion of the femoral neck Two patients were checked in the orthopaedic department and had normal findings The remaining five patients are included in the present follow up study Three of them had values of the AV angle 1 2 S D above the mean value and two had normal values except for a difference between the right and left sides of 5 and 7 degrees respectively Thus over 50 per cent of the patients who received prolonged treatment showed increased anteversion of the femoral neck

The relation between increased anteversion of the femoral neck and CDH has been explained by different opposing theories Alvik (1962) regarded the increased anteversion as one of the manifestations of CDH possibly genetically determined Others have regarded the increased anteversion as a secondary phenomenon possibly due to muscular inactivity or special therapeutic procedures (Tettweis 1971 Papadopulos 1971 Sommerville 1974) Different theories of pathogenesis for the latter hypothesis have been proposed Tettweis (1971) holds the view that muscular imbalance produces uneven pressure upon the epiphysis and leads to uneven development of the growth of the skeleton Papadopulos (1971) advocates the theory of relative hypertrophy of muscles affecting the rotation movement of the hip

If the sloping acetabular roof with an indistinctly marked lateral margin and a small epiphysis of the femoral head are characteristics of the dysplastic hip (Bjerkreim 1974), it may be noted that no correlation was found between increased anteversion of the femoral neck and dysplastic changes in the present investigation

One of the most important questions is whether abduction splinting may have an untoward influence upon the normal development of the hip joint

As early as 1961 Palmen reported two cases with fragmentation of the femoral head after the ordinary splinting therapy Later similar observations have been made by others (Dabadie 1971) The potential danger of avascular necrosis after abduction splinting has recently been stressed by Mears (1974) but strongly opposed by Fredensborg (1976) Siffert et al (1973) warn against the extreme frog position which produces abnormal pressure on the anterior part of the acetabulum and results in failure of normal development Bjerkreim (1974) states that it is not likely that the pillow treatment is harmful to the hip joint In any case it is justified to conclude that avascular necrosis of the femoral head represents a relatively rare complication However I have not been able to find any controlled investigation of possible other adverse effects of the splinting therapy

The first months of life represent an extremely important period of the child s motor development and it would be surprising if the relative inactivity of the lower extremities in the maximally abducted position should not produce a muscular imbalance with secondary changes in the bony structures Three muscles are important for both abduction and internal rotation of the hip, namely gluteus medius gluteus minimus

and the tensor fasciae latea. Partial atrophy and shortening of special muscle *groups may finally* lead to inward rotation of the femur, and the effect may be more marked in individuals with less developed muscles (slender subjects, patients with muscular atrophies of various origin a o).

The possible harmful effect of abduction therapy might be verified by splinting healthy children with stable hips at birth Such a project is however unacceptable on ethical grounds Another approach to the problem is a systematic follow-up study of children with unstable hips at birth which are left untreated. The group of children examined in the present investigation is too small to allow any definite conclusions, but one gains a strong impression that abduction splinting represents at least one of the pathogenetic factors for the increased anteversion of the femoral neck

The beneficial effect of splinting against luxation, subluxation and serious dysplastic changes of the hip is undisputable, in spite of the fact that some cases are "missed" at birth and a certain number do not respond to apparently correct therapy. However, in regions where instability of the hip joint appears relatively frequently (Trondheim 22 4 per thousand) the present therapeutic regime possibly leads to pathological development of the hip in 2–4 children per thousand liveborn This number is too high and indicates the necessity of finding more selective criteria of therapy of the newborn

The results of the present investigation have shown an asymmetrical development of the hip joint in a well defined group of children Differences of the AV-angle between the right and left hip exceeding 10° were found in 28 per cent in group A and 23 per cent in group B On average the values for the right side were higher than those for the left No certain explanation for these findings can be presented, but the clue to the *problem* may well be found in the well-known habitual oblique position assumed by many infants Palmen (1976) has *found* the habitual oblique position to be the cause of one-sided limited abduction of the hip in about two per cent of infants

Discussion of the indications for derotational osteotomy in cases with increased anteversion of the femoral neck is outside the scope of this project In view of the present investigation one would tend to advocate a more "dynamic" view of the therapy, and at least in some patients consider physiotherapy as a possible alternative to operative treatment (Scholder 1967)

SUMMARY

Among 6509 newborn instability of the hip joint was found in 146 (22 4 per thousand liveborns) All of them were treated with Frejka's cusion splint, usually for three months Eleven patients required additional treatment with a plaster cast, and in four a derotational osteotomy was performed

During infancy the children showed several deviations from the normal motor development, the most important being an increased abduction and an increased external rotation capacity of the hip joint A small group of infants showed a gradual increase of the passive internal rotation from 40–50 degrees to 80–90 degrees

In 129 patients a detailed clinical and radiological follow-up study was performed at the age of four to six years, and the results were compared with those of 100 healthy children and 17 children with unstable hips at birth left untreated

Clinical examination at the age of four to six years showed that about 20 per cent of the girls and about 10 per cent of the boys with unstable hips treated with abduction had abnormal function of the hip The most important findings were

increased internal rotation and decreased external rotation in girls and increased abduction in boys

Radiological examination of the treated group of affected children showed pathological values of the angles measured in 30 per cent of the girls and in 10 per cent of the boys In girls pathological mean values were demonstrated for all angles measured (AC, CE, CCD and AV), whereas the boys displayed pathological values of the AV angle only

The mean angle values of the untreated children with unstable hips at birth showed no significant deviation from the values of the control group

A positive correlation was demonstrated between the values of the AC-angle and the CE-angle, but no correlation could be demonstrated between the AVangle and the other angles

Slender children showed significantly higher values for the AV-angle than children with a low height/weight ratio

Seven of eleven children who received prolonged treatment with a plaster cast showed pronounced anteversion of the femoral neck Increased anteversion of the femoral neck was also demonstrated in three patients with concomitant muscular abnormalities

It is suggested that increased anteversion of the femoral neck is a secondary phenomenon in CDH, possibly because of relative muscular inactivity, and that abduction splintage may be a causative factor

APPENDIX

Results of the radiological examination of 129 children with unstable hips at birth treated with an abduction splint (group A), 100 healthy children (group B) and 17 children with unstable hips at birth left untreated (group C). The excluded numbers represent subjects not followed up

ACKNOWLEDGEMENTS

The present investigation was carried out at the *Maternity Hospital, E C Dahls Stiftelse* and the Obstetrical Department and the Pediatric Clinic of the Regional Hospital of Trondheim in the years 1969 to 1976

I wish to thank Dr Kurt Palmen who stimulated my interest in congenital dysplasia of the hip joint during my work in Falkoping in 1960 I am greatly indebted to Professor Per Edvardsen for his great interest and fruitful discussions during the present project My thanks also to Dr Ingjald Bjerkreim Dr Victor Segalstad and Dr Einar Sudman for valuable medical advice

I am grateful to Dr Johan Olsen for allowing the use of data of the children born in Bergen and to Dr Karl Maurseth for valuable support during the radiological studies

M Sc Paul Rusten has carried out the technical part of the computer work and helped me *with the statistical analysis For this I am very* grateful

Thanks are also given to the technical assistants Liv Hofstad Tøndel, Ingrid Hagen and Marit Stiklestad for valuable help during the radiological examination Miss Ruth Hunstad has been of great help in sorting and classifying the medical records My thanks also to Mr Bjørn Tonning for photographic service, Mr Thor Stuedal who is responsible for the illustrations and Dr Barbara Baird who has corrected the English text

To all collegues nurses and technicians who have helped me in different ways *I wish to express my gratitude*

I have received financial support from the Regional Hospital of Trondheim, the University of Trondheim and Trøndelag Medisinske Selskap I wish to thank Director Jarle Øie, Professor Jon Lamvik and Dr Terje Aamodt for this support. The work was supported by grants from "Norges Almenvitenskapelige Forskningsråd"

PART ONE

A CLINICAL AND RADIOLOGICAL STUDY

by

Olle Lansinger and Lars Irstam

Chapter 1

INTRODUCTION

Acetabular fractures have since long attracted interest In 1575 Ambroise Paré stated that "there is thus danger in the dislocation of the hip that either the bone cannot be put into place again at least unless with much trouble, or else, being put in that it will presently fall out again" According to Nicoll (1966) this statement referred to fractures of the acetabulum which could either obstruct reduction or render it unstable

Acetabular fractures with *central* dislocation of the femoral head were described by Calissen in 1778 (Schroeder 1909) In later years central acetabular fractures have been described with increasing frequency (Westerborn 1954, Stewart & Milford 1954, Rowe & Lowell 1961, Judet, Judet & Letournel 1964, Lehtonen 1968)

Posterior acetabular fractures were described in the 19th Century by Cooper (1824) and Malgaigne (1855) During the first 50 years of the 20th Century few reports were published on posterior acetabular fractures In the middle of 1950 a careful study was carried out by Waller (1955) who examined 106 such fractures of a total of 2334 pelvic fractures during the period 1945 1954 He found that during this 10-year period there was an increase from 2 per cent to 8 per cent which he ascribed to increasing traffic accidents

As regards the *classification* of *central* acetabular fractures no general agreement seems to have been reached so far Stewart & Milford (1954), Eichenholtz & Stark (1964) and Pearson & Hargadon (1962) based their different classifications of central acetabular fractures on the degree of central protrusion of the femoral head Knight & Smith (1958), Rowe & Lowell (1961) and Judet Judet & Letournel (1964) found it more important to take account of the distribution of the fracture lines

Posterior acetabular fractures are as a rule classified depending on the degree of dislocation of the acetabular fragment the comminution of the fracture and the stability of the joint (Thompson & Epstein 1951, Epstein 1961, 1974, Stewart & Milford 1954, Waller 1955)

As for *treatment* of acetabular fractures opinions differ

Central fracture-dislocations offer some problems in that the surgical technique is difficult Conservative measures have therefore been recommended (Bohler 1966, Stewart et al 1975). There are few comparative studies of different treatments something which further adds to the problem of evaluation

Posterior acetabular fractures without posterior dislocation of the femoral head and without posterior displacement of the acetabular fragment are treated either with traction or early mobilization without weight-bearing (Waller 1955)

Chapter 1

INTRODUCTION

Acetabular fractures have since long attracted interest In 1575 Ambroise Paré stated that there is thus danger in the dislocation of the hip that either the bone cannot be put into place again at least unless with much trouble or else, being put in that it will presently fall out again According to Nicoll (1966) this statement referred to fractures of the acetabulum which could either obstruct reduction or render it unstable

Acetabular fractures with *central* dislocation of the femoral head were described by Calissen in 1778 (Schroeder 1909) In later years central acetabular fractures have been described with increasing frequency (Westerborn 1954 Stewart & Milford 1954, Rowe & Lowell 1961, Judet, Judet & Letournel 1964 Lehtonen 1968)

Posterior acetabular fractures were described in the 19th Century by Cooper (1824) and Malgaigne (1855) During the first 50 years of the 20th Century few reports were published on posterior acetabular fractures In the middle of 1950 a careful study was carried out by Waller (1955) who examined 106 such fractures of a total of 2334 pelvic fractures during the period 1945 1954 He found that during this 10-year period there was an increase from 2 per cent to 8 per cent which he ascribed to increasing traffic accidents

As regards the *classification* of *central* acetabular fractures no general agreement seems to have been reached so far Stewart & Milford (1954) Eichenholtz & Stark (1964) and Pearson & Hargadon (1962) based their different classifications of central acetabular fractures on the degree of central protrusion of the femoral head Knight & Smith (1958), Rowe & Lowell (1961) and Judet Judet & Letournel (1964) found it more important to take account of the distribution of the fracture lines

Posterior acetabular fractures are as a rule classified depending on the degree of dislocation of the acetabular fragment the comminution of the fracture and the stability of the joint (Thompson & Epstein 1951 Epstein 1961 1974 Stewart & Milford 1954, Waller 1955)

As for *treatment* of acetabular fractures opinions differ

Central fracture-dislocations offer some problems in that the surgical technique is difficult Conservative measures have therefore been recommended (Bohler 1966, Stewart et al 1975) There are few comparative studies of different treatments something which further adds to the problem of evaluation

Posterior acetabular fractures without posterior dislocation of the femoral head and without posterior displacement of the acetabular fragment are treated either with traction or early mobilization without weight-bearing (Waller 1955)

Posterior acetabular fractures in combination with posterior dislocation of the femoral head (posterior fracture dislocations) are as a rule treated by closed reduction of the femoral head followed by open fixation of the acetabular fragment (Waller 1955, Epstein 1974, Ender 1976), but the conservative approach with traction is also used (Bohler 1954, Brav 1962, Nerubay et al. 1973).

The object of the present investigation has been:

1. To carry out a clinical study based on 124 acetabular fractures in 123 patients treated during 1963-1973 at the Departments of Orthopaedic Surgery I and II, Sahlgren Hospital, Goteborg. Special consideration has been taken to frequency, classification, radiographic appearance, cause of injury, associated injuries and treatment.

2. To perform a clinical follow-up study of 101 hips in 100 patients during April 1974-January 1975.

3. To carry out a radiologic study with special reference to possible development of post-injury osteoarthrosis and avascular necrosis of the femoral head

BASIC MATERIAL
A STUDY OF 123 PATIENTS AND A REVIEW OF LITERATURE

Material

The material consists of 123 patients with 124 fractures admitted during 1963 1973 to the Departments of Orthopaedic Surgery I and II, Sahlgren Hospital, Goteborg

Age and sex

Age and sex are presented in Figure 1 The men represent 68 per cent (82 patients) and the women 32 per cent (41 patients) The youngest patient was a 14-year-old girl and the oldest an 86-year-old lady The mean age for the men was 47 years and for the women 51 The mean age for the total material was 49 years The distribution of age with the peak incidence between 40-60 years corresponds well with the reports in the literature (Waller 1955, Trojan & Perschl 1956, Wechselberger 1956)

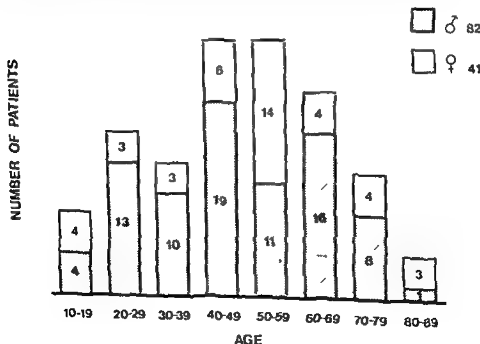

Fig 1 Age and sex distribution in 123 patients with acetabular fractures.

Side of injury

Of the 124 fractures 61 were on the right side and 63 on the left.

Frequency

In 1928 Westerbom reported on 293 pelvic fractures. Among these he found 51 (47 central and 4 posterior) acetabular fractures, i.e. 17.4 per cent.

In 1943 Wilenius described 88 (82 central and 6 posterior) acetabular fractures in 428 pelvic fractures collected between 1922-1939, i.e. 20.6 per cent.

An increase from 2 to 8 per cent in posterior acetabular fractures over a 10 year-period was noted by Waller (1955) in 2334 *pelvic fractures.*

Wechselberger (1956) reported on 159 acetabular fractures in 754 pelvic fractures, i.e. 21 per cent.

In a material of 407 pelvic fractures Huittinen & Slatis (1972) found 103 acetabular fractures, i.e. 25.3 per cent.

Solheim & Skrede (1973) found central and posterior acetabular fractures in 11 per cent of all *pelvic fractures which represented 0.4 per cent of all fractures studied.*

Present investigation

During 1963-1973 648 patients with pelvic fractures were treated at the Sahlgren Hospital, Goteborg. Among these, 123 had acetabular fractures, i.e. 19 per cent which corresponds well with the frequencies reported in the literature.

Classification of acetabular fractures

Anatomy of the acetabulum

The acetabulum forms the central meeting point of the os ischium, the os ilium and the os pubis. It forms a deep circular socket for the articulating femoral head. Rowe & Lowell (1961) have divided the acetabulum into a superior, posterior and inner part. The superior third of the acetabulum, the superior dome, is the main weight bearing area of the joint, and the posterior third has a stabilizing effect. The inner part of the acetabulum is much more thin-walled than the remaining acetabulum and increases the stability of the joint.

Judet, Judet & Letournel (1964) stated: "We consider the acetabulum to be located in the concavity of an arch formed by two columns of bone, one anterior and the other posterior. These columns converge and meet in a thick and compact zone of bone which is always spared by fractures of the acetabulum. This zone is situated below and in front of the iliac articular surface of the sacroiliac joint. The posterior or ilioischial column which is voluminous and thick descends caudad as far as the ischial tuberosity. This column is composed of the vertical portion of the ischium and of that portion of the ilium immediately above the ischium. On the anterolateral surface of the column lies the posterior part of the articular surface of the acetabulum, the posterior acetabular rim. On the medial surface of this column is the quadri

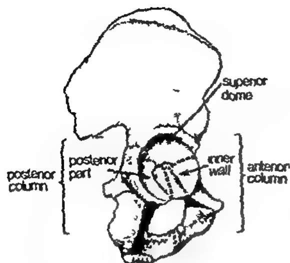

Fig 2 A External aspect of right acetabulum.

Fig 2 B Internal aspect of right acetabulum.

lateral surface The anterior or iliopubic column runs obliquely downward inward and anteriorly making an angle of about 60 degrees with the posterior column The anterior column consists of a short segment of the ilium and of the pubis and extends up as far as the anterior inferior iliac spine On the posterolateral surface of this column lies the anterior part of the articular surface of the acetabulum the anterior acetabular rim These two columns form an arch in which the superior angle or key-stone is formed by a rounded plate of compact iliac bone the roof of the acetabulum" (Figs 2 A and 2 B)

Central acetabular fractures

There are many suggestions on the classification of central acetabular fractures Some authors make their classification according to the degree of central dislocation of the femoral head (Stewart & Milford 1954 Eichenholtz & Stark 1964) Others find it more important to take account of the distribution of fracture lines and which part of the acetabulum that becomes involved (Knight & Smith 1958 Rowe & Lowell 1961 Judet Judet & Letournel 1964)

Stewart & Milford (1954) have suggested the following classification

Grade I Linear and stellate fractures through the floor of the acetabulum No dislocation of the femoral head

Grade II Comminuted fractures with a mild to moderate central displacement of the femoral head and of the acetabular fragments

Grade III Marked displacement of the fragments and protrusion of the head of the femur into the pelvis with or without comminution of the superior portion of the acetabulum

Side of injury

Of the 124 fractures 61 were on the right side and 63 on the left

Frequency

In 1928 Westerbom reported on 293 pelvic fractures. Among these he found 51 (47 central and 4 posterior) acetabular fractures, i e. 17.4 per cent

In 1943 Wilenius described 88 (82 central and 6 posterior) acetabular fractures in 428 pelvic fractures collected between 1922-1939, i e. 20.6 per cent.

An increase from 2 to 8 per cent in posterior acetabular fractures over a 10 year period was noted by Waller (1955) in 2334 pelvic fractures.

Wechselberger (1956) reported on 159 acetabular fractures in 754 pelvic fractures, i e. 21 per cent.

In a material of 407 pelvic fractures Huittinen & Slatis (1972) found 103 acetabular fractures, i.e. 25.3 per cent.

Solheim & Skrede (1973) found central and posterior acetabular fractures in 11 per cent of all pelvic fractures which represented 0.4 per cent of all fractures studied

Present investigation

During 1963-1973 648 patients with pelvic fractures were treated at the Sahlgren Hospital, Goteborg. Among these, 123 had acetabular fractures, i e 19 per cent which corresponds well with the frequencies reported in the literature.

Classification of acetabular fractures

Anatomy of the acetabulum

The acetabulum forms the central meeting point of the os ischium, the os ilium and the os pubis It forms a deep circular socket for the articulating femoral head Rowe & Lowell (1961) have divided the acetabulum into a superior, posterior and inner part The superior third of the acetabulum, the superior dome, is the main weight bearing area of the joint, and the posterior third has a stabilizing effect The inner part of the acetabulum is much more thin-walled than the remaining acetabulum and increases the stability of the joint

Judet, Judet & Letournel (1964) stated "We consider the acetabulum to be located in the concavity of an arch formed by two columns of bone, one anterior and the other posterior These columns converge and meet in a thick and compact zone of bone which is always spared by fractures of the acetabulum. This zone is situated below and in front of the iliac articular surface of the sacroiliac joint. The posterior or ilioischial column which is voluminous and thick descends caudad as far as the ischial tuberosity This column is composed of the vertical portion of the ischium and of that portion of the ilium immediately above the ischium On the anterolateral surface of the column lies the posterior part of the articular surface of the acetabulum, the posterior acetabular rim On the medial surface of this column is the quadri

Judet, Judet & Letournel (1964) made a classification according to the involvement of the "iliopubic bone" as a fracture of the anterior column and to the involvement of the "ilio ischial bone" as a fracture of the posterior column Their classification is therefore

Isolated fractures of the columns (Fig. 3)

Pure transverse fractures (Fig. 4)

Combined fractures of both columns (Fig 5)

Mixed fractures (Fig 6)

Present investigation

In the present investigation the central dislocation of the femoral head and the appearance of the superior dome have been estimated and a classification similar to that of Stewart & Milford (1954) has been used

The position of the femoral head was classified as follows

no dislocation

mild to moderate dislocation < 15 millimeters of the centre of the femoral head in a central direction

severe dislocation central dislocation ≥ 15 millimeters

Mode of measurement

On AP views the lower borders of the sacro-iliac joints were combined by a horizontal line drawn across the pelvis The center for each femoral head was determined and from each center a perpendicular was drawn to intersect with the horizontal pelvic line The distance from the point where the perpendicular through the centre of the femoral head met the horizontal

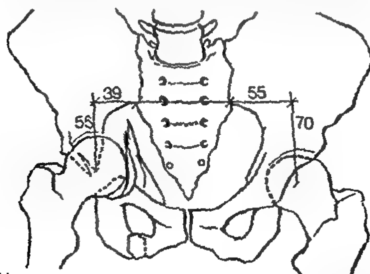

Fig 7 Schematic illustration of measurement of the central dislocation of the femoral head in a patient with a severe central dislocation of the femoral head where the fracture involves the superior dome

Fig 3 Right acetabulum with an isolated fracture of the posterior column

Fig 4 Right acetabulum with a transverse fracture

Fig 5 Right acetabulum with a T fracture

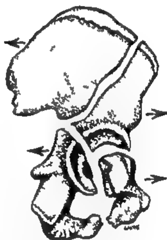

Fig 6 Right acetabulum with a mixed fracture involving the iliac wing besides the two columns

Grade IV : Central dislocation with an associated fracture of the head or neck of the femur

Rowe & Lowell (1961) have classified their acetabular fractures into four groups (Group I III and IV are central fractures)

Group I Linear undisplaced fractures with either single or stellate lines

Group II Posterior fractures with a small rim fracture or a large displaced posterior sector

Group III Innerwall fractures with minor moderate and severe intrapelvic displacement of the femoral head

Group IV Superior and bursting fractures with varying degree of disruption of the acetabular socket

Judet, Judet & Letournel (1964) made a classification according to the involvement of the "iliopubic bone" as a fracture of the anterior column and to the involvement of the "ilio-ischial bone" as a fracture of the posterior column. Their classification is therefore

Isolated fractures of the columns (Fig. 3)

Pure transverse fractures (Fig. 4)

Combined fractures of both columns (Fig. 5)

Mixed fractures (Fig. 6)

Present investigation

In the present investigation the central dislocation of the femoral head and the appearance of the superior dome have been estimated and a classification similar to that of Stewart & Milford (1954) has been used.

The position of the femoral head was classified as follows

no dislocation

mild to moderate dislocation < 15 millimeters of the centre of the femoral head in a central direction

severe dislocation central dislocation ≥ 15 millimeters

Mode of measurement

On AP views the lower borders of the sacro-iliac joints were combined by a horizontal line drawn across the pelvis. The center for each femoral head was determined and from each center a perpendicular was drawn to intersect with the horizontal pelvic line. The distance from the point where the perpendicular through the centre of the femoral head met the horizontal

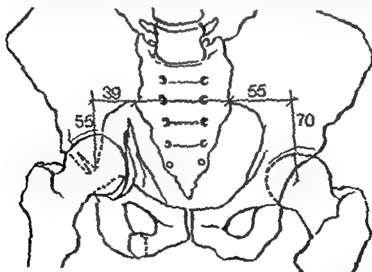

Fig. 7. Schematic illustration of measurement of the central dislocation of the femoral head in a patient with a severe central dislocation of the femoral head where the fracture involves the superior dome

pelvic line was then measured on each side to the lower border of the sacro iliac joint (Fig 7) The difference in distance decided the degree of medial dislocation The same comparison of distance was made along the perpendicular to obtain information of the degree of superior dislocation

Classification of own material

I Central fractures without central dislocation of the femoral head (Fig 8)
  A – Without displacement of the acetabular fragments
  B – With displacement of the acetabular fragments

II Central fractures with mild to moderate central dislocation of the femoral head (Fig 9)
  A – The superior dome intact
  B – The superior dome fractured

III Central fractures with severe central dislocation of the femoral head (Fig 10)
  A – The superior dome intact
  B – The superior dome fractured

Central fractures in 85 patients are presented in Table 1 Age and sex distribution for patients with central acetabular fractures is presented in Figure 11

Fig 8 Radiograph of a central acetabular fracture without central dislocation of the femoral head in the right hip in a 37 year-old male

Fig 9 Radiograph of a central acetabular fracture with mild to moderate central dislocation of the femoral head where the superior dome is intact in the right hip in a 64-year-old male

Fig 10 Radiograph of a central acetabular fracture with severe central dislocation of the femoral head where the superior dome is fractured in the right hip in a 59-year-old female

pelvic line was then measured on each side to the lower border of the sacro iliac joint (Fig 7) The difference in distance decided the degree of medial dislocation The same comparison of distance was made along the perpendicular to obtain information of the degree of superior dislocation

Classification of own material

I Central fractures without central dislocation of the femoral head (Fig 8)
 A – Without displacement of the acetabular fragments
 B – With displacement of the acetabular fragments

II Central fractures with mild to moderate central dislocation of the femoral head (Fig 9)
 A – The superior dome intact
 B – The superior dome fractured

III Central fractures with severe central dislocation of the femoral head (Fig 10)
 A – The superior dome intact
 B – The superior dome fractured

Central fractures in 85 patients are presented in Table 1 Age and sex distribution for patients with central acetabular fractures is presented in Figure 11

Table 1. *Classification of central acetabular fractures, 85 patients*

Type of fracture	Number of patients
Central fracture without central dislocation of the femoral head	
Without displacement of the acetabular fragments	19
With displacement of the acetabular fragments	26
Central fracture with mild to moderate central dislocation of the femoral head	
The superior dome intact	11
The superior dome fractured	8
Central fracture with severe central dislocation of the femoral head	
The superior dome intact	5
The superior dome fractured	16
Total	85

Posterior acetabular fractures

Thompson & Epstein (1951) suggested the following classification for posterior fracture dislocations of the hip

Type I Posterior dislocation of the femoral head without fracture or with no more than minor fracture of the posterior rim

Type II Posterior dislocation of the femoral head with a large single fracture of the posterior rim

Type III Posterior dislocation of the femoral head with a comminute fracture of the posterior rim.

Type IV Posterior dislocation of the femoral head with a fracture of both the rim and the floor of the acetabulum

Type V Posterior dislocation of the femoral head with fracture of the femoral head with or without other fractures

Stewart & Milford (1954) used a similar classification dividing their posterior fractures into four grades which corresponded to Type I II III and V in the classification made by Thompson & Epstein

Waller (1955) divided his posterior fractures into three types

Type I Fracture of the posterior superior part with no or only moderate displacement of the fragment (Fig 12)

Type II Fracture with a single fragment of the posterior part with extensive displacement and usually dislocation of the femoral head (Fig 13)

Type III Comminute fractures (Fig 14)

Some authors have not found it necessary to subdivide posterior acetabular fractures into various types like e g Rowe & Lowell (1961) and Judet Judet & Letournel (1964)

Present investigation

For this investigation the classification of Waller (1955) has been used In Table 2 a presentation of the types of posterior fractures in 39 patients is given Four patients were classified as Type I 15 as Type II and 20 as Type III

Table 2 *Posterior acetabular fractures in 39 patients classified according to Waller (1955)*

Type of fracture	Number of patients
Type I	4
Type II	15
Type III	20
Total	[illegible]

Fig 12 Radiograph of a posterior acetabular fracture Type I in a 44 year-old male

Fig 13 Radiograph of a posterior acetabular fracture Type II in a 24 year-old male

Fig 14 Radiograph of a posterior acetabular fracture Type III in a 23 year-old male

Of 39 posterior fractures, 32 were combined with a posterior dislocation of the femoral head Thus, there was no femoral head dislocation in 7 and of these 4 were classified as Type I and 3 as Type III

Age and sex distribution for patients with posterior fractures is presented in Figure 15

Comment In 7 patients there were fractures of combined posterior and central types These were classified according to the fracture which appeared radiographically dominating Five of these were central fractures which in addition had a minor fracture of the posterior acetabular rim without displacement Two were posterior fracture-dislocations which in addition had central fractures one without displacement of the acetabular fragments and one with a comminute central fracture with displacement of the acetabular fragments

The radiographic appearance of the hip joint in the diagnosis of acetabular fractures

In 1955 Waller pointed out that a reliable radiologic view of the acetabulum could not be obtained only by AP (anteroposterior) and lateral projections "The anterior and posterior acetabular margins are sometimes completely or partly superimposed and the head of the femur obscures the view Since routine radiologic examinations mainly are confined to these projections posterior acetabular fractures might be overlooked "

In 1948 Urist described a series of 15 cases of posterior acetabular fractures of which 4 were not observed at the primary radiologic examination

In 1955 Waller found 12 neglected cases in a material of 106 posterior acetabular fractures

In 1968 d'Aubigné stated "among the last 100 cases of old dislocation of the hip 47 were probably unrecognized in the hospital where they were admitted in emergency "

Fig 16 B Anteroposterior view of right hip with a posterior acetabular fracture

Fig 16 C The same patient examined with a posterior oblique view according to Waller illustrating the size of the fragment and degree of displacement

Anteroposterior view

The normal AP radiograph of the hip shows a number of characteristics which are necessary to recognize (Fig 17)

1 *The superior channel*, a roentgenographic line corresponding to the arcuate line, which begins at the superior edge of the greater sciatic notch and extends downward to the pubic tubercle (a break in this line indicates fracture of the iliopubic column)
2 The ilio ischial roentgenographic line formed by the posterior four fifths of the quadrilateral surface of the pelvic bone (see Fig 2 B)
3 The roentgenographic U, composed laterally of the most inferior and anterior portion of the acetabular fossa and medially of the anterior flat part of the quadrilateral surface (normally the U and the ilio ischial line intersect or are tangential)
4 The roof of the acetabulum, which is prolonged in a lateral to medial direction to end on the lateral branch of the U
5 The edge of the anterior lip of the acetabulum
6 The edge of the posterior lip of the acetabulum

Waller in 1955 stressed the importance of oblique projections in posterior acetabular fractures. He suggested the following procedure: the patient is placed semiprone on the examination table with the injured hip down and the healthy side up (Fig. 16 A). The patient supports himself on one hand and on the flexed healthy leg so that he lies in approximately 45 degrees semiprone position. Supported by a few sandbags placed under the chest and thighs, the patient does not exert pressure on the injured hip. The x-ray tube is directed from behind at an angle of 10 degrees cranially and is centered on the gluteal fold. In this position the beams run tangentially to the upper acetabular rim which is depicted on the radiograph as a sharply arched line, which continues medially to form the posterior boundary of the incisura acetabuli. The postero superior part of the acetabulum is depicted unobscured by other skeletal parts (Figs. 16 B and 16 C).

In central fracture dislocation of the hip the AP view demonstrates disruption of the acetabulum. However, it may be difficult in this view to determine accurately the extent of displacement and the exact location of the fractured fragments.

Judet, Judet & Letournel (1964) suggest the following projections in the radiologic diagnosis of acetabular fractures.

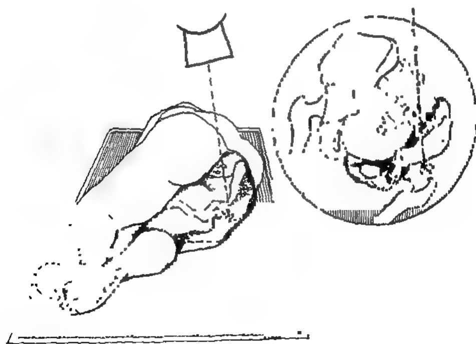

Fig 16 A Patient in semiprone position for radiographic demonstration of fracture of the posterior rim of right acetabulum according to Waller

Fig 16 B Anteroposterior view of right hip with a posterior acetabular fracture

Fig 16 C. The same patient examined with a posterior oblique view according to Waller il lustrating the size of the fragment and degree of displacement

Anteroposterior view

The normal AP radiograph of the hip shows a number of characteristics which are necessary to recognize (Fig. 17)

1 The superior channel, a roentgenographic line corresponding to the arcuate line, which begins at the superior edge of the greater sciatic notch and extends downward to the pubic tubercle (a break in this line indicates fracture of the iliopubic column)

2 The ilio-ischial roentgenographic line formed by the posterior four fifths of the quadri lateral surface of the pelvic bone (see Fig 2 B)

3 The roentgenographic U composed laterally of the most inferior and anterior portion of the acetabular fossa and medially of the anterior flat part of the quadrilateral surface (normally the U and the ilio ischial line intersect or are tangential)

4 The roof of the acetabulum, which is prolonged in a lateral to medial direction to end on the lateral branch of the U

5 The edge of the anterior lip of the acetabulum

6 The edge of the posterior lip of the acetabulum

Waller in 1955 stressed the importance of oblique projections in posterior acetabular fractures He suggested the following procedure the patient is placed semiprone on the examination table with the injured hip down and the healthy side up (Fig 16 A) The patient supports himself on one hand and on the flexed healthy leg so that he lies in approximately 45 degrees semiprone position Supported by a few sandbags placed under the chest and thighs, the patient does not exert pressure on the injured hip The x ray tube is directed from behind at an angle of 10 degrees cranially and is centered on the gluteal fold In this position the beams run tangentially to the upper acetabular rim which is depicted on the radiograph as a sharply arched line, which continues medially to form the posterior boundary of the incisura acetabuli The postero superior part of the acetabulum is depicted unobscured by other skeletal parts (Figs 16 B and 16 C)

In central fracture dislocation of the hip the AP view demonstrates disruption of the acetabulum However, it may be difficult in this view to determine accurately the extent of displacement and the exact location of the fractured fragments

Judet, Judet & Letournel (1964) suggest the following projections in the radiologic diagnosis of acetabular fractures

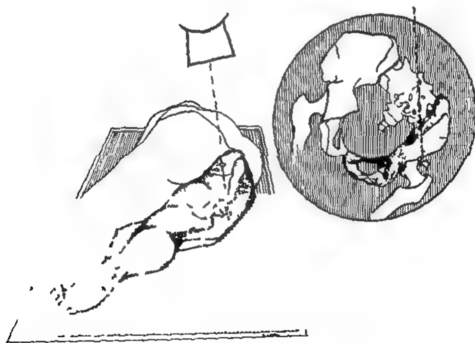

Fig 16 A Patient in semiprone position for radiographic demonstration of fracture of the posterior rim of right acetabulum according to Waller

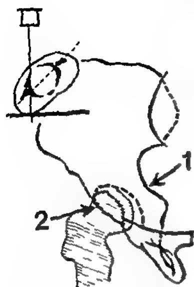

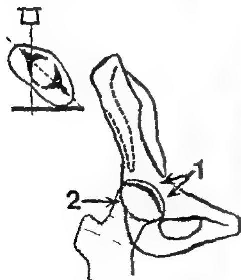

Fig 18 External oblique view of right normal hip in schematic illustrat on and in radiograph (Patient in supine position and rotated 45° to the right) 1) Posterior edge of the ilium 2) Anterior lip of the ace tabulum.

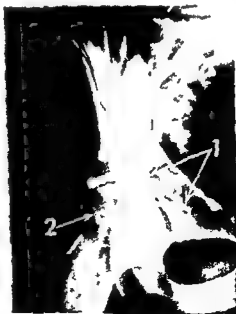

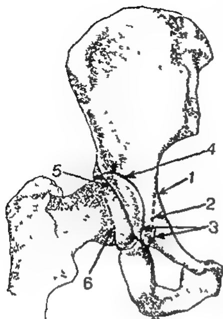

Fig 19 Internal obaque view of right normal h p in schematic illustration and in radiograph (Patient in supine position and rotated 45° to the left.) 1) Iliopubic column 2) Posterior lip of the acetabulum.

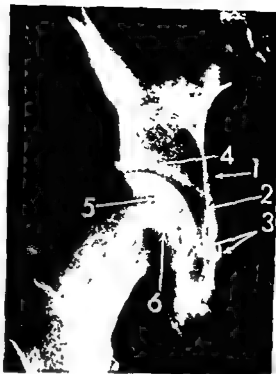

Fig 17 Schematic illustration and radiographic AP view of right hip showing 1) superior channel, the arcuate line, 2) ilio-ischial roentgenographic line, 3) roentgenographic U, 4) roof of the acetabulum, 5) anterior lip of the acetabulum, and 6) posterior lip of the acetabulum (From Judet, Judet & Letournel J Bone Jt Surg 1964, vol 46–A, p 1616, Fig 2)

External oblique view

The three-quarter external oblique view – the alar projection – (Fig. 18) spreads out the iliac wing and the quadrilateral surface allowing the study of the posterior edge of the iliac bone and the anterior lip of the acetabulum.

Internal oblique view

The three-quarter internal oblique view – the obturator foramen projection – (Fig 19) shows the entire iliopubic column in profile whereas the wing of the ilium is perpendicular to the film and viewed on edge This projection also enables one to follow the posterior lip of the acetabulum prolonged by the curve of the posterior "horn" of the acetabular articular surface.

Present investigation

The cause of injury is presented in Table 3. Road accidents were responsible in 61 per cent (75 of 123 patients). The remaining were due to falls from heights and on the same level excepting one who was involved in a rail road accident and one in a tram accident. A relation of the frequency of fractures to the frequency of traffic accidents involving personal injury was made and is presented in Table 4.

1971	1482	7	4.7
1972	1341	9	6.7
1973	1356	3	2.2

Present investigation

The 85 patients with central acetabular fractures were all radiologically examined at the time of injury with AP views. In addition 3 patients were examined with oblique views according to the technique described by Judet, Judet & Letournel.

The 39 patients with posterior acetabular fractures were at the time of injury examined with AP views and in most of them a lateral projection was also made. In addition 7 were examined with oblique projections and 3 with tomography.

Comment. Only 3 of the 85 patients with central acetabular fractures were examined with oblique projections. Fourty-five patients had central fractures without central dislocation of the femoral head and the treatment was for these patients strictly conservative. Further radiologic examination might for this reason have been regarded as superfluous Fourty patients had a central dislocation of the femoral head. In these cases the AP view demonstrated the disruption of the acetabulum, but it was sometimes difficult to determine accurately the extent of displacement and the exact location of the fractured fragments. However, even in these cases the therapeutic approach was conservative (35 of 40).

The 39 patients with posterior acetabular fractures were examined at the time of injury with AP projections and in most of them a lateral projection was also made. The lateral projection is important in the straight posterior dislocation of the femoral head which sometimes can be difficult to detect on an AP view. The straight lateral projection gives a good view of the acetabulum as this projection is close to the en-face view of the acetabulum Seven patients were in addition examined with oblique projections and in 3 cases with tomography. The technique described by Waller (1955) was used and this examination was performed in 5 cases after closed reduction of the dislocated femoral head in order to get a more exact view of the size and position of the posterior acetabular fragment

Cause of injury

On perusing the literature it becomes apparent that acetabular fractures of both central and posterior types mostly occur as a sequence to traffic accidents.

Waller 1955 found that 69 per cent of 106 so called dash board fractures were due to traffic accidents Lehtonen (1968) reported on traffic accidents as the cause of acetabular fractures during two periods. He found that between 1933 and 1953 traffic accidents were the cause in 45 per cent and between 1954 and 1962 there was an increase to 70 per cent. Gothlin & Hindmarsh (1970) reported on 120 central fractures and found road accidents to be the cause in 66 per cent Nerubay et al (1973) presented a material of 107 patients of whom 81 per cent were victims in road accidents Stewart et al (1975) found the cause to be traffic accidents in no less than 85 per cent of 220 cases of both fractures and dislocations Vecsei (1975) studied the cause of injury between 1967 and 1973 and reported on 30 fractures all of which were obtained in traffic accidents

Present investigation

The cause of injury is presented in Table 3. Road accidents were responsible in 61 *per cent* (75 of 123 patients). The remaining were due to falls from heights and on the same level excepting one who was involved in a rail road accident and one in a tram accident. A relation of the frequency of fractures to the frequency of traffic accidents involving personal injury was made and is presented in Table 4.

1970	1398	3	2.2
1971	1482	7	4.7
1972	1341	9	6.7
1973	1356	3	2.2

Comment In the present investigation the major cause of acetabular fractures was traffic accidents Central fractures appeared mostly when the victim was hit directly by a moving object In 15 of the 75 road accidents the central fracture was obtained with the patient still in the car Sufficiently detailed information is difficult to obtain in each individual case as the sequence of events happens so fast that the patient cannot give an account of all particulars concerning the infliction of violence and position of the extremities It may well be that all 15 patients had a direct blow to the trochanteric region A blow against the knee and a sub sequent posterior fracture occurred in no less than 29 of 39 fractures This latter development corresponds well with the experience of e g Waller (1955)

Associated injuries

As a rule the trauma which causes an acetabular fracture is so violent in nature that other injuries arise simultaneously Thus both soft and other skeletal tissues can become involved Any variety of associated injury may occur and Trojan & Perschl (1956) have listed no less than 46 different lesions accompanying acetabular fractures In 79 acetabular fractures there was an associated injury in 55 7 per cent and in 10 patients the severity was such that death followed Wechselberger (1956) reported on 57 acetabular fractures which were associated with other injuries in no less than 33 instances (58 per cent) Six patients died Nerubay et al (1973) *reported a frequency of 41 per cent with associated skeletal injuries and 36 per* cent with associated visceral injuries in 111 acetabular fractures

Present investigation

For this investigation a distinction has been made between visceral and skeletal associated injuries They are presented in Tables 5 and 6

Comment It must be remembered that one patient representing one acetabular fracture could have more than one associated injury

It is thus evident from the tables that visceral injury was found in combination with ace tabular fracture in 13 per cent and other skeletal injury in 49 per cent No difference was noted in incidence between central and posterior fractures as regards skeletal injuries For associated visceral injury this accompanied central fractures in 12 per cent and posterior frac tures in 15 per cent

As additional information it must be mentioned that Tables 5 and 6 do not comprise the following associated injuries which did not fall under the headings of the tables There were 5 patients with posterior fracture of whom one had a dislocation of the humeroscapular joint one an anterior dislocation of the contralateral hip without fracture one a dislocation of the patella on the same side one a rupture of the anterior cruciate ligament on the ipsilateral knee and one a dislocation of the elbow

Table 5 *Associated visceral injuries in 16 123 patients (10 in the central and 6 in the posterior group)*

Type of injury	Central fractures No. of patients	Posterior fractures No. of patients	Total
Cerebral concussion	7	4	11
Pneumothorax	0	2	2

Clinical appearance

Central acetabular fractures

Often patients with acetabular fractures have other injuries which may distract the examiner, who therefore can overlook the possibility of a hip condition. The patient will, however, complain of pain around the trochanteric region and in the groin. In extensive central fractures with a large hemorrhage there may be complaints of abdominal pain and the lower abdomen is tender on palpation and a slight défense musculaire might be palpable. However, testing the motion of the hip joint will always yield pain which should arise suspicion of a fracture and a radiologic examination should be carried out.

Comment. In the present investigation the major cause of acetabular fractures was traffic accidents. Central fractures appeared mostly when the victim was hit directly by a moving object. In 15 of the 75 road accidents the central fracture was obtained with the patient still in the car. Sufficiently detailed information is difficult to obtain in each individual case as the sequence of events happens so fast that the patient cannot give an account of all particulars concerning the infliction of violence and position of the extremities. It may well be that all 15 patients had a direct blow to the trochanteric region. A blow against the knee and a subsequent posterior fracture occurred in no less than 29 of 39 fractures. This latter development corresponds well with the experience of e g. Waller (1955).

Associated injuries

As a rule the trauma which causes an acetabular fracture is so violent in nature that other injuries arise simultaneously. Thus, both soft and other skeletal tissues can become involved Any variety of associated injury may occur and Trojan & Perschl (1956) have listed no less than 46 different lesions accompanying acetabular fractures. In 79 acetabular fractures there was an associated injury in 55.7 per cent and in 10 patients the severity was such that death followed. Wechselberger (1956) reported on 57 acetabular fractures which were associated with other injuries in no less than 33 instances (58 per cent) Six patients died. Nerubay et al. (1973) reported a frequency of 41 per cent with associated skeletal injuries and 36 per cent with associated visceral injuries in 111 acetabular fractures.

Present investigation

For this investigation a distinction has been made between visceral and skeletal associated injuries. They are presented in Tables 5 and 6.

Comment. It must be remembered that one patient representing one acetabular fracture could have more than one associated injury.

It is thus evident from the tables that visceral injury was found in combination with acetabular fracture in 13 per cent and other skeletal injury in 49 per cent. No difference was noted in incidence between central and posterior fractures as regards skeletal injuries. For associated visceral injury this accompanied central fractures in 12 per cent and posterior fractures in 15 per cent

As additional information it must be mentioned that Tables 5 and 6 do not comprise the following associated injuries which did not fall under the headings of the tables. There were 5 patients with posterior fracture of whom one had a dislocation of the humeroscapular joint, one an anterior dislocation of the contralateral hip without fracture, one a dislocation of the patella on the same side, one a rupture of the anterior cruciate ligament on the ipsilateral knee and one a dislocation of the elbow

Table 5 *Associated visceral injuries in 16/123 patients (10 in the central and 6 in the posterior group)*

Type of injury	Central fractures No. of patients	Posterior fractures No. of patients	Total
Cerebral concussion	7	4	11
Pneumothorax	0	2	2
Rupture of the diaphragm	1	0	1
Rupture of the urinary bladder	3	0	3
Rupture of the aorta	1	0	1
Pulmonary contusion	2	1	3

Table 6 *Associated skeletal injuries in 60/123 patients (38 in the central and 22 in the posterior group)*

Site of fracture	Central fractures No. of patients	Posterior fractures No. of patients	Total
Face	3	10	13
Upper extremity	17	8	25
Chest	8	9	17
Spinal column	5	0	5
Femoral head	0	2	2
Femoral neck, medial and lateral	5	1	6
Great trochanter	2	0	2
Femoral shaft	2	1	3
Patella	0	4	4
Other site in lower extremity	13	3	16

Clinical appearance

Central acetabular fractures

Often patients with acetabular fractures have other injuries which may distract the examiner, who therefore can overlook the possibility of a hip condition. The patient will, however, complain of pain around the trochanteric region and in the groin. In extensive central fractures with a large hemorrhage there may be complaints of abdominal pain and the lower abdomen is tender on palpation and a slight défense musculaire might be palpable. However, testing the motion of the hip joint will always yield pain which should arise suspicion of a fracture and a radiologic examination should be carried out.

Posterior acetabular fractures

Posterior acetabular fractures can be difficult to detect especially in the absence of posterior dislocation of the femoral head. The trauma producing the acetabular fracture is often so great that the patient may sustain other injuries which distract attention from the hip region. Injuries of the acetabulum may therefore be overlooked initially (Waller 1955, d'Aubigné 1968).

In cases of posterior fracture-dislocation the typical position of the leg – adduction, inward rotation and shortening – usually betrays the character of the injury. The knee joint is often flexed and the big toe often rests upon the tarsus of the other foot. The femoral head may be felt in its posterior position. Passive and active movement of the injured hip is painful and abduction in particular is restricted.

In fractures with no dislocation of the femoral head and no or only slight dislocation of the acetabular fragment, the clinical picture is less clear. The leg of the injured side assumes no characteristic position and the femoral head cannot be felt.

In cases with patellar fractures sustained in the sitting position of an automobile driver, or passenger, special caution is required as a hip lesion may be present but overlooked.

"The essential safeguard against this error are, firstly to insist always on a full clinical survey of the whole body in cases of major injury, and secondly to make sure that the radiographs in every case of fractured femoral shaft take in the whole length of the bone and include the hip joint" (Adams 1972).

Symptoms from the sciatic nerve occur in a varying degree in posterior acetabular fractures and figures from 6 to 35 per cent have been reported. Stewart & Milford (1954) and Stewart et al. (1975) reported 13 and 19 per cent nerve injuries respectively. Waller (1955) in a material of 106 posterior acetabular fractures reported 22.6 per cent and Rowe & Lowell (1961) observed as many as 35 per cent. Brav (1962) reported 6 7 per cent. Epstein (1974) registered 13 per cent sciatic lesions in his material of posterior fracture-dislocations of the hip.

All authors who have described nerve injuries stress the importance of searching for the symptoms as early as possible

Sciatic nerve injuries

Injury to the sciatic nerve is a common complication in association with fracture-dislocation of the hip (Stewart & Milford 1954, Waller 1955, Stewart et al 1975). As mentioned above the frequencies of sciatic nerve palsy generally lie between 6 and 35 per cent

The risk of damage to the sciatic nerve is great in posterior fracture-dislocations, due to the exposed position of the nerve, where it leaves the infrapiriform foramen to continue downwards close to the posterior acetabular rim Fractures of the acetabular rim with displacement of the fragments carry a great risk of injury to the nerve either as simple stretching or as laceration of the nerve by displaced fragments (Waller 1955)

Present investigation

Sciatic nerve involvement with peroneal paresis was registered in 8 patients Seven had a

posterior fracture-dislocation and one a central acetabular fracture without central dislocation of the femoral head. At follow-up the paresis remained in 5 patients.

Case reports

1. 62-year-old man with a central acetabular fracture without dislocation of the femoral head but with a slightly medially dislocated fragment of the acetabulum. He was treated with the extremity of the injured side on a sledge. After 1 week a peroneal paresis was detected. This remained at the time of follow-up 2 years following the injury.

2. 58-year-old woman with a posterior fracture-dislocation. Type III. She was operated immediately because of the peroneal paresis. At the operation a large posterior fragment was observed being dislocated cranially and posteriorly. The sciatic nerve was squeezed and hematomatous. The nerve was placed back in its original position after the fracture had been fixed with two screws. At follow-up 5½ years after the injury there was still a partial peroneal paresis.

3. 24-year-old man with a posterior fracture-dislocation. Type II. A large posterior fragment was dislocated posteriorly. Because of the patient's bad general condition operation was not done until 4 weeks had elapsed. At operation a sharp fragment directed against the sciatic nerve was detected. The sciatic nerve was freed and put aside and the acetabular fragment was fixed with a cancellous screw. Eleven years following the injury a partial peroneal paresis remained.

4. 42-year-old man with a posterior fracture-dislocation. Type III. The patient was admitted to another hospital and the posterior fracture-dislocation was overlooked. After 2 months the dislocation was observed. There was a total peroneal paresis which still remained 11 years following the injury.

5. 50-year-old woman with a posterior fracture-dislocation. Type III. Acute reduction with good replacement of the fragments. Treated by traction for 6 weeks. At follow-up 2 years later there was still a partial peroneal paresis.

6. 21-year-old man with a posterior fracture-dislocation. Type II. Because of the patient's bad general condition the dislocation was not reduced until after 8 days when the patient was operated still unconscious. The sciatic nerve was freed and the acetabular fragment put into place and fixed with two pins. At the follow-up after 4 years the paresis was gone.

7. 22-year-old man with a posterior fracture-dislocation. Type III. Acute reduction of the femoral head was performed and the acetabular fragments fell into place. The first 5 days a partial peroneal paresis was noticed. After 2 weeks the paresis was gone.

8. 33-year-old man with a posterior fracture-dislocation. Type III. Operation was performed after 3 days and the fragments were put into place and fixed with two pins. During the operation the sciatic nerve was identified as normal. He was treated with traction for 6 weeks, and after 2 weeks a partial peroneal paresis was noticed. At the follow-up after 3 years the patient had no symptoms of peroneal paresis.

Comments. The division of the sciatic nerve into its two main branches, the tibial and peroneal nerves, is demonstrable already at the origin of the nerve trunc from the lumbosacral plexus. The nerve fibers of the tibial and peroneal nerves run quite separately but perineural fibrous tissue binds the two branches together so that they present as a single nerve to the naked eye. The peroneal portion of the sciatic nerve always lies laterally, i.e. close to the posterior acetabular rim. Thus, this branch is more exposed to injury by e.g. displaced fracture fragments from the posterior acetabular rim. These anatomical circumstances explain the clinical observation that peroneal paresis is a fairly common complication in these fractures (Walker 1955).

Treatment of acetabular fractures

Treatment of central acetabular fractures. A review of literature

Central acetabular fractures without central dislocation of the femoral head or the acetabular fragments are generally treated by conservative methods. Some recommend bed rest only (Rowe & Lowell 1961, Judet, Judet & Letournel 1964, Solheim & Skrede 1973) and others a short period of traction (Wechselberger 1956, Pearson & Hargadon 1962, Eichenholtz & Stark 1964).

However, there is a diversity of opinion on the treatment of central acetabular fractures with central dislocation of the femoral head. There are many who advocate a rather strict conservative line of treatment (Eichenholtz & Stark 1964, Nicoll 1966, Bohler 1966, Tipton et al 1975, Jahna 1976) and many who advocate surgical treatment (Armstrong 1948, Westerborn 1954, Judet, Judet & Letournel 1964, Letournel 1966, Paleari & Gualtieri 1971) Further on some surgeons point out that most central dislocations should and can best be treated by conservative methods and recommend open reduction and osteosynthesis only in fractures engaging the superior dome where closed treatment has failed in reducing both the femoral head and the acetabular roof accurately (Rowe & Lowell 1961, Gothlin & Hindmarsh 1970, Carnsale et al 1975)

There is, however, a general consensus of opinion that the ultimate aim should be as perfect a restoration of the acetabular-femoral head relationship as possible Maintenance of the congruity between the acetabular surfaces and the head of the femur is regarded as the important goal in the treatment of these fractures (Gothlin & Hindmarsh 1970, Carnsale et al 1975, Tipton et al 1975).

However, this goal is sometimes difficult to achieve and incongruity between the articular surfaces becomes accepted as this in many cases do not seem to result in impaired function (Rowe & Lowell 1961, Austin 1971, Tipton et al 1975).

Conservative treatment

Many writers regard bed rest as an adequate therapy in the case of acetabular fracture without displacement (Rowe & Lowell 1961, Judet, Judet & Letournel 1964). In the treatment of central fracture-dislocations traction has for many decades been used as the principle means of achieving reduction and preserving the correct position In the application of traction a variety of techniques have been employed. Traction has been applied either as skin traction (Pearson & Hargadon 1962) or via a pin through the femoral condyles or through the tibial tuberosity or pins through the proximal femur, with the traction in a lateral direction (Lipscomb 1961) Double traction has frequently been used, i e longitudinal and lateral traction in conjunction (Gelehrter 1969 Renné & Schmelzeisen 1975, Tipton et al 1975)

Some authors have emphasized the importance of reduction performed under general anesthesia, in severe cases (Tipton et al. 1975).

As regards the duration of traction, opinions differ. Periods up to 12 weeks have been reported (Carnesale et al 1975, Tipton et al. 1975)

Urist (1947 1948) reported on 16 patients with central fracture-dislocations Irrespective of the position of the femoral head there was a good response to conservative treatment with traction and at follow up 1 3 years later the results were interpreted as excellent However in bursting fractures where reduction was impossible conservative treatment resulted in great disability He therefore suggested either fusion or arthroplasty for this latter group

In 1954 Stewart & Milford reviewed 193 patients with fracture-dislocation of the hip Twenty-eight of these had central fractures and 23 were treated conservatively Seven years later a follow up comprised 18 of the conservatively treated patients and 9 of these exhibited excellent or good results whereas the results in the remaining 9 were fair or poor

Stewart et al (1975) reported on 23 conservatively treated patients and found that the results in 11 were excellent or good and in 12 fair or poor They stated the innerwall fractures and explosive dome fractures of the acetabulum that are not suitable for open reduction (and very few are) can best be treated by skeletal traction"

In 1961 Rowe & Lowell described a series of 93 patients with fractures of the acetabulum with and without dislocation of the femoral head There were 76 central fractures and of these 64 were treated conservatively The average time of follow up was 6 years and the results were excellent or good in 80 per cent (51 of 64) fair in 12 per cent (8 of 64) and poor in 8 per cent (5 of 64) In linear undisplaced fractures there were 100 per cent excellent or good results in the innerwall fractures 90 per cent excellent or good results and in the superior dome fractures 37 per cent excellent or good results and 63 per cent fair or poor results These authors stated that the important factor was the reduction of the femoral head to its normal position under the dome They found surgical reduction of the displaced central wall of the acetabulum unnecessary and the only indication for operation of central fractures was bursting or severely displaced fractures engaging the superior dome

In 1962 Pearson & Hargadon reviewed 80 patients with fractures and fracture-dislocations of the central part of the acetabulum The results in 50 patients all of whom were treated conservatively were reported with an account of three clinical types of fractures Type I and II were central fractures without central dislocation of the femoral head and Type III was central fractures with a central protrusion of the femoral head Mean time for follow up was 2 5 years The overall results in their three groups were good and the patients had minor complaints They found good or excellent results in more than 60 per cent In the two groups in which there was no central protrusion of the femoral head the results were good or excellent in more than 90 per cent These authors found these fractures to be adequately treated with simple measures such as rest and a short period of skin traction The results in patients with a central protrusion of the femoral head were worse than in those without central protrusion However 15 patients of 23 with central dislocation of the femoral head had no or only slight pain (65 per cent) They found better results in patients (12) in whom closed reduction was not attempted

In 1964 Eichenholtz & Stark made a review of 35 patients with central acetabular fractures They divided their fractures into three types based on the degree of penetration of the femoral head into the pelvis Twenty-eight patients were treated conservatively and 21 of these were followed up Sixteen (75 per cent) achieved satisfactory results Six patients were operated

Treatment of acetabular fractures

Treatment of central acetabular fractures. A review of literature

Central acetabular fractures without central dislocation of the femoral head or the acetabular fragments are generally treated by conservative methods. Some recommend bed rest only (Rowe & Lowell 1961, Judet, Judet & Letournel 1964, Solheim & Skrede 1973) and others a short period of traction (Wechselberger 1956, Pearson & Hargadon 1962, Eichenholtz & Stark 1964)

However, there is a diversity of opinion on the treatment of central acetabular fractures with central dislocation of the femoral head. There are many who advocate a rather strict conservative line of treatment (Eichenholtz & Stark 1964, Nicoll 1966, Bohler 1966, Tipton et al 1975, Jahna 1976) and many who advocate surgical treatment (Armstrong 1948, Westerborn 1954, Judet, Judet & Letournel 1964, Letournel 1966, Paleari & Gualtieri 1971) Further on some surgeons point out that most central dislocations should and can best be treated by conservative methods and recommend open reduction and osteosynthesis only in fractures engaging the superior dome where closed treatment has failed in reducing both the femoral head and the acetabular roof accurately (Rowe & Lowell 1961, Gothlin & Hindmarsh 1970, Carnsale et al 1975)

There is, however, a general consensus of opinion that the ultimate aim should be as perfect a restoration of the acetabular-femoral head relationship as possible Maintenance of the congruity between the acetabular surfaces and the head of the femur is regarded as the important goal in the treatment of these fractures (Gothlin & Hindmarsh 1970, Carnsale et al 1975, Tipton et al 1975).

However, this goal is sometimes difficult to achieve and incongruity between the articular surfaces becomes accepted as this in many cases do not seem to result in impaired function (Rowe & Lowell 1961, Austin 1971, Tipton et al. 1975).

Conservative treatment

Many writers regard bed rest as an adequate therapy in the case of acetabular fracture without displacement (Rowe & Lowell 1961, Judet, Judet & Letournel 1964) In the treatment of central fracture-dislocations traction has for many decades been used as the principle means of achieving reduction and preserving the correct position In the application of traction a variety of techniques have been employed. Traction has been applied either as skin traction (Pearson & Hargadon 1962) or via a pin through the femoral condyles or through the tibial tuberosity or pins through the proximal femur, with the traction in a lateral direction (Lipscomb 1961) Double traction has frequently been used, i e longitudinal and lateral traction in conjunction (Gelehrter 1969, Renné & Schmelzeisen 1975, Tipton et al 1975)

Some authors have emphasized the importance of reduction performed under general anesthesia, in severe cases (Tipton et al 1975).

As regards the duration of traction, opinions differ. Periods up to 12 weeks have been reported (Carnesale et al. 1975, Tipton et al. 1975)

Crist (1947 1948) reported on 16 patients with central fracture-dislocations Irrespective of the position of the femoral head there was a good response to conservative treatment with traction and at [illegible] follow-up 1 3 years later the results were interpreted as *excellent However in bursting fractures* where reduction was impossible conservative treatment resulted in great disability He therefore suggested either fusion or arthroplasty for this latter group

In 1954 Stewart & Milford reviewed 193 patients with fracture-dislocation of the hip Twenty-eight of these had central fractures and 23 were treated conservatively Seven years later a follow up comprised 18 of the conservatively treated patients and 9 of these exhibited excellent or good results whereas the results in the remaining 9 were fair or poor

Stewart et al (1975) reported on 23 conservatively treated patients and found that the results in 11 were excellent or good and in 12 fair or poor They stated the innerwall fractures and explosive dome fractures of the acetabulum that are not suitable for open reduction (and very few are) can best be treated by skeletal traction"

In 1961 Rowe & Lowell described a series of 93 patients with fractures of the acetabulum with and without dislocation of the femoral head There were 76 central fractures and of these 64 were treated conservatively The average time of follow up was 6 years and the results were excellent or good in 80 per cent (51 of 64) fair in 12 per cent (8 of 64) and poor in 8 per cent (5 of 64) In linear undisplaced fractures there were 100 per cent excellent or good results in the innerwall fractures 90 per cent excellent or good results and in the superior dome fractures 37 per cent excellent or good results and 63 per cent fair or poor results These authors stated that the important factor was the reduction of the femoral head to its normal position under the dome They found surgical reduction of the displaced central wall of the acetabulum unnecessary and the only indication for operation of central fractures was bursting or severely displaced fractures engaging the superior dome

In 1962 Pearson & Hargadon reviewed [illegible] patients with fractures and fracture-dislocations of the central part of the acetabulum The results in 50 patients all of whom were treated conservatively were reported with an account of three clinical types of fractures Type I and II were central fractures without central dislocation of the femoral head and Type III was central fractures with a central protrusion of the femoral head Mean time for follow up was 2 5 years The overall results in their three groups were good and the patients had minor complaints They found good or excellent results in more than 60 per cent In the two groups in which there was no central protrusion of the femoral head the results were good or excellent in more than 90 per cent These authors found these fractures to be adequately treated with simple measures such as rest and a short period of skin traction The results in patients with a central protrusion of the femoral head were worse than in those without central protrusion However 15 patients of 23 with central dislocation of the femoral head had no or only slight pain (65 per cent) They found better results in patients (12) in whom closed reduction was not attempted

In 1964 Lichenholtz & Stark made a review of 35 patients with central acetabular fractures They divided their fractures into three types based on the degree of penetration of the femoral head into the pelvis Twenty-eight patients were treated conservatively and 21 of these were followed up Sixteen (75 per cent) achieved satisfactory results Six patients were operated

upon and in 5 the results were satisfactory. These authors believe that traction is valuable in early treatment of displaced fractures even if there is no intrapelvic protrusion of the femoral head, in order to minimize pain and diminish deformity. According to their experience a stabilization will occur after 2 4 weeks so that no further traction is necessary and very little displacement will take place. However, they stress that weight-bearing must be avoided for at least 4 months. They pointed out the ability of the hip joint to produce a new acetabulum in patients with displaced fractures. An autogenous intrapelvic mold arthroplasty was produced Thus, they recommended closed treatment for central acetabular fractures

In 1975 Tipton et al. reviewed 24 patients with central fracture-dislocation of the hip All patients were treated conservatively with traction through the tibial tuberosity or combined traction. They used the same classification as Rowe & Lowell (1961) and their material comprised 15 patients with innerwall fractures and 8 of these had excellent or good results Nine patients had superior dome or bursting fractures and 6 of these achieved good results However, of the 15 patients with innerwall fractures 5 of 7 treated with combined traction had good or excellent results, and of the patients with superior dome fractures 5 of 6 treated with combined traction had good results. These authors recommend conservative treatment for central fracture dislocations with combined traction for 12 weeks

Further authors with experience of conservative treatment claim satisfactory results in 70-90 per cent (Gothlin & Hindmarsh 1970, Austin 1971, Solheim & Skrede 1973, Nerubay et al 1973).

In Table 7 a summary is given of the results of conservative treatment of central acetabular fractures as reported in the literature.

Surgical treatment

The possibilities of surgical treatment were discussed as early as in the beginning of this century (Tillmans 1905, ref. Lehtonen 1968). As the surgical technique is regarded as cumbersome and difficult operative treatment was for long time resorted to only in occasional cases The first open reduction was performed by Vaughn in 1912 and Levin in 1943 was the first to use internal fixation in the treatment of central acetabular fractures (Barnes & Stewart 1976) During the last 15 years thorough studies by French investigators have been published Operations for acetabular fractures were undertaken after careful consideration on the basis of pathoanatomical findings and were performed using screws and other devices for fixation (Judet, Judet & Letournel 1964, Judet & Letournel 1974).

In 1948 Armstrong described 101 patients with fracture-dislocation of the hip Fifty patients were followed up and 7 of these had central acetabular fractures All 7 patients were treated conservatively and they all developed osteoarthrosis Based on this he suggested that in cases of central fractures an arthrodesis should be primarily performed

In 1928 Westerborn reported 500 cases of pelvic fractures The acetabular floor was fractured in 64 and in 21 the femoral head was dislocated centrally to a varying degree In 1954 the author reviewed 51 of the 64 patients Only 26 (51 per cent) recovered to the working capacity they had had previous to injury and 25 (49 per cent) were more or less disabled He recommended cup arthroplasty in central fracture-dislocation.

upon and in 5 the results were satisfactory These authors believe that traction is valuable in early treatment of displaced fractures even if there is no intrapelvic protrusion of the femoral head, in order to minimize pain and diminish deformity According to their experience a stabilization will occur after 2 4 weeks so that no further traction is necessary and very little displacement will take place However, they stress that weight bearing must be avoided for at least 4 months They pointed out the ability of the hip joint to produce a new acetabulum in patients with displaced fractures An autogenous intrapelvic mold arthroplasty was produced Thus, they recommended closed treatment for central acetabular fractures

In 1975 Tipton et al reviewed 24 patients with central fracture dislocation of the hip All patients were treated conservatively with traction through the tibial tuberosity or combined traction They used the same classification as Rowe & Lowell (1961) and their material comprised 15 patients with innerwall fractures and 8 of these had excellent or good results Nine patients had superior dome or bursting fractures and 6 of these achieved good results However of the 15 patients with innerwall fractures 5 of 7 treated with combined traction had good or excellent results, and of the patients with superior dome fractures 5 of 6 treated with combined traction had good results These authors recommend conservative treatment for central fracture dislocations with combined traction for 12 weeks

Further authors with experience of conservative treatment claim satisfactory results in 70-90 per cent (Gothlin & Hindmarsh 1970, Austin 1971, Solheim & Skrede 1973, Nerubay et al 1973)

In Table 7 a summary is given of the results of conservative treatment of central acetabular fractures as reported in the literature

Surgical treatment

The possibilities of surgical treatment were discussed as early as in the beginning of this century (Tillmans 1905, ref Lehtonen 1968) As the surgical technique is regarded as cumbersome and difficult operative treatment was for long time resorted to only in occasional cases The first open reduction was performed by Vaughn in 1912 and Levin in 1943 was the first to use internal fixation in the treatment of central acetabular fractures (Barnes & Stewart 1976) During the last 15 years thorough studies by French investigators have been published Operations for acetabular fractures were undertaken after careful consideration on the basis of pathoanatomical findings and were performed using screws and other devices for fixation (Judet Judet & Letournel 1964 Judet & Letournel 1974)

In 1948 Armstrong described 101 patients with fracture dislocation of the hip Fifty patients were followed up and 7 of these had central acetabular fractures All 7 patients were treated conservatively and they all developed osteoarthrosis Based on this he suggested that in cases of central fractures an arthrodesis should be primarily performed

In 1928 Westerborn reported 500 cases of pelvic fractures The acetabular floor was fractured in 64 and in 21 the femoral head was dislocated centrally to a varying degree In 1954 the author reviewed 51 of the 64 patients Only 26 (51 per cent) recovered to the working capacity they had had previous to injury and 25 (49 per cent) were more or less disabled He recommended cup-arthroplasty in central fracture-dislocation

Judet, Judet & Letournel (1964) recommended that all acetabular fractures with displacement should be treated with open reduction and osteosynthesis of the acetabular fragments They carefully described the classification and surgical approach for these fractures. In 1974 Judet & Letournel reported on 244 patients with acetabular fractures, all treated surgically Sixty-four of these had posterior fractures and 180 central fractures (*fractures of the iliopubic column, fractures of the ilioischial column, transverse fractures and mixed fractures*) Results were excellent in 67 per cent, good in 17 per cent, fair in 8 per cent and poor in 8 per cent

Vecsei in 1975 reviewed 30 patients with fracture-dislocation of the hip which were operated upon in Vienna between 1965 and 1973. Twenty-six of these were given an adequate follow up. He used a classification like Judet, Judet & Letournel (1964) Sixteen of these fractures were central fracture-dislocations and he found excellent results in 5, good in 7, fair in 2, and poor in 2.

Johansson & Olerud (1971) reported on 16 operated patients and their preliminary impression of the results were satisfactory. Experience of the same kind has been reported by Elliott (1956), Pafeari & Gualtieri (1971) and Batra (1976).

In Table 7 a summary is given of the results of surgical treatment of central acetabular fractures as reported in the literature.

Present investigation

The material of central acetabular fractures for the present investigation consisted of 85 patients with 85 fractures. Of these 5 were treated *surgically* Of 80 patients treated *conservatively* there was no central dislocation of the femoral head in 45 Thirty five patients had a central dislocation of the femoral head of varying degree. Sixteen of these had the superior dome intact and 19 had not.

Table 8 gives the type of fracture and their treatment and Table 9 the time for immobilization and hospital stay

Details of treatment

Central fractures without dislocation of the femoral head (45 patients)

A – Without displacement of the acetabular fragments (19 patients)
All patients were immobilized in bed Only one was put into traction for one week Time of immobilization was 2 3 weeks No information could be obtained when weight-bearing was instituted

B – With displacement of the acetabular fragments (26 patients)
All patients were immobilized in bed, two only were put into traction Traction through the tibial tuberosity was maintained in one patient for 2 weeks and in the other for 4 weeks The mean time of immobilization was 3 weeks and following this a non weight bearing period for 2-3 weeks was prescribed.

Table 8 *Type and treatment of 85 central acetabular fractures*

Type of fracture	No of patients	
	Treated conservatively	Treated surgically
Central fracture without central dislocation of the femoral head		
Without displacement of the acetabular fragments	19	
With displacement of the acetabular fragments	26	
Central fracture with mild to moderate central dislocation of the femoral head		
The superior dome intact	11	
The superior dome fractured	8	
Central fracture with severe central dislocation of the femoral head		
The superior dome intact	5	
The superior dome fractured	11	5

Table 9 *Mean times of immobilization and hospital stay for patients with central acetabular fractures treated conservatively and surgically*

Type of fracture	Treated conservatively		Treated surgically	
	Immobilization (weeks)	Hospital stay (weeks)	Immobilization (weeks)	Hospital stay (weeks)
Central fractures without central dislocation of the femoral head	2–3	3 4		
Central fractures with mild to moderate central dislocation of the femoral head	4 5	6 7		
Central fractures with severe central dislocation of the femoral head	6 7	9 10	6 7	16

Central acetabular fractures with mild to moderate central dislocation of the femoral head (19 patients)

A – Superior dome intact (11 patients)
Seven patients were immobilized in bed without traction Four were treated by traction through the tibial tuberosity Time of immobilization was 4 5 weeks followed by a 4 week period of non weight bearing

B – Superior dome fractured (8 patients)
Two patients were immobilized in bed without traction Six were treated by traction applied through the tibial tuberosity Time of immobilization and non weight bearing was the same as under A

Of those 10 patients who were treated by traction through the tibial tuberosity a good reduction of the femoral head was obtained in 8 In 4 of these the superior dome was intact and in the remaining 4 the superior dome was fractured

With good reduction of the femoral head [redacted] meant that the femoral head has been reduced to its normal position Any further differentiation into acceptable poor and no reduction has not been made Those cases in which the femoral head has not been reduced to its normal position will in the following be called less satisfactory reduction

Central fractures with severe central dislocation of the femoral head treated conservatively (16 patients)

A – Superior dome intact (5 patients)
Three patients were immobilized in bed without traction Two were treated with traction (One with closed reduction under anesthesia followed by traction through the proximal femur one with a combined traction through the tibial tuberosity and proximal femur) Time of immobilization was 6 7 weeks The time for non weight bearing has not been obtained

B – Superior dome fractured (11 patients)
Four patients were immobilized in bed without traction Seven were treated by traction which was supplied through the tibial tuberosity in 2 In addition 5 had a traction applied to the proximal femur Moreover one patient was treated with closed reduction under general anesthesia (This patient was for 3 weeks put into traction through the tibial tuberosity but this gave no reduction of the femoral head After 3 weeks a closed reduction under anesthesia was performed and a lateral traction through the proximal femur was applied) Time of immobilization was 6 7 weeks The period of non weight bearing has not been obtained

Of those 16 patients with central fractures with severe central dislocation of the femoral head 9 were treated with traction In 6 of these (4 with superior dome involvement) a good reduction was obtained of the centrally dislocated femoral head In 3 reduction was less satisfactory

In 2 cases traction through the tibial tuberosity was applied which did not yield a satisfactory reduction of the femoral head In 5 cases the traction through the tibial tuberosity was combined with lateral traction through the proximal femur and in 4 of these a good reduction of the femoral head was obtained In 2 cases a manual reduction in general anesthesia was carried out, it was combined with traction through the tibial tuberosity and proximal femur in one of them and through the proximal femur only in the other In both cases a good reduction was obtained

Central acetabular fractures with severe central dislocation of the femoral head treated surgically (5 patients)

Five patients were treated with open reduction and osteosynthesis Four of these were postoperatively put into traction which was applied through the tibial tuberosity Mean time of immobilization was 6-7 weeks

Case reports

1 43 year-old woman The femoral head was at the time of injury dislocated medially-cranially 45 mm At the operation the acetabular fragment was fixed with a cerclage Reduction of the femoral head was not achieved and postoperatively it was still dislocated 40-45 mm

2 52 year-old man The femoral head was dislocated medially-cranially 20 mm The acetabular fragment was fixed with one screw Postoperatively the femoral head remained dislocated 20 mm

3 17 year-old woman The femoral head was dislocated 20 mm medially The acetabular fragments were fixed with two plates and screws There was a good reduction of the femoral head and postoperatively the femoral head was in its normal position

4 23 year-old woman The femoral head was dislocated medially-cranially 20 mm The fragments were fixed with three cerclages There was a good reduction of the femoral head (Fig 28)

5 36-year-old man The femoral head was dislocated medially-cranially 25 mm The acetabular fragments were fixed with a plate and four screws One did not succeed in reducing the femoral head to its normal position and postoperatively the femoral head was dislocated 15 mm medially

Comment The majority of cases with central dislocation of the femoral head has been treated conservatively Traction treatment has been resorted to and in most cases this has been applied through the tibial tuberosity In 7 patients lateral traction was applied to the proximal femur This is according to many (e g Lipscomb 1961 Lidstrom 1961, Nicoll 1966) the most logic way of applying traction when the femoral head is dislocated centrally as the line of traction then will be in allignment with the axis of the femoral neck Little influence seems however to be exerted on the acetabular fragments When the fractured acetabulum exhibits a persistent dislocation of the fragments despite traction, open reduction appears indicated One of the arguments advanced by those who advocate surgical intervention, is that only by operative means a restoration of the acetabular fragments can be obtained and along with this an acceptable position of the femoral head

On the other hand some authors (Rowe & Lowell 1961, Eichenholtz & Stark 1964, Austin 1971) have the opinion that the realignment is unnecessary for good results They were im

Central acetabular fractures with mild to moderate central dislocation of the femoral head (19 patients)

A – Superior dome intact (11 patients).
Seven patients were immobilized in bed without traction. Four were treated by traction through the tibial tuberosity Time of immobilization was 4-5 weeks followed by a 4-week period of non-weight bearing.

B – Superior dome fractured (8 patients).
Two patients were immobilized in bed without traction. Six were treated by traction applied through the tibial tuberosity Time of immobilization and non weight bearing was the same as under A

Of those 10 patients who were treated by traction through the tibial tuberosity a good reduction of the femoral head was obtained in 8. In 4 of these the superior dome was intact and in the remaining 4 the superior dome was fractured

With good reduction of the femoral head is meant that the femoral head has been reduced to its normal position Any further differentiation into acceptable, poor and no reduction has not been made Those cases in which the femoral head has not been reduced to its normal position will in the following be called less satisfactory reduction

Central fractures with severe central dislocation of the femoral head treated conservatively (16 patients)

A – Superior dome intact (5 patients)
Three patients were immobilized in bed without traction Two were treated with traction (One with closed reduction under anesthesia followed by traction through the proximal femur, one with a combined traction through the tibial tuberosity and proximal femur) Time of immobilization was 6-7 weeks The time for non weight bearing has not been obtained

B – Superior dome fractured (11 patients)
Four patients were immobilized in bed without traction Seven were treated by traction which was supplied through the tibial tuberosity in 2 In addition 5 had a traction applied to the proximal femur Moreover one patient was treated with closed reduction under general anesthesia (This patient was for 3 weeks put into traction through the tibial tuberosity but this gave no reduction of the femoral head After 3 weeks a closed reduction under anesthesia was performed and a lateral traction through the proximal femur was applied) Time of immobilization was 6 7 weeks The period of non weight bearing has not been obtained

Of those 16 patients with central fractures with severe central dislocation of the femoral head 9 were treated with traction In 6 of these (4 with superior dome involvement) a good reduction was obtained of the centrally dislocated femoral head In 3 reduction was less satisfactory

Stewart & Milford (1954) collected 193 patients with fracture-dislocations of the hip over a 30 year period Adequate follow up was made in 123 patients Of these 96 had posterior fractures These authors made a classification of posterior fracture-dislocation into four grades where Grade I was a posterior dislocation of the femoral head with no or only a slight fracture of the posterior rim without consequence and Grade IV was a posterior dislocation of the femoral head with a fracture of the femoral neck Posterior dislocation of the femoral head with a large single fragment or a comminute fracture of the posterior acetabular rim (Grade II and III respectively) accounted for 57 patients Fourty two of these were treated conservatively Sixteen were reported with excellent or good results 26 with fair or poor results Fifteen patients were treated surgically Six had excellent or good results and 9 had fair or poor results Mean time for follow up was 7 years These authors stress the importance of early treatment and advised open procedures only when closed reduction failed when the joint was unstable after closed reduction of the femoral head and when at radiologic examination loose fragments were found in the joint

Waller (1955) gave an account of 106 patients with posterior acetabular fractures collected over a 10 year period Follow up examinations were available in 87 patients with a mean time for follow-up for 3 years and 11 months Of the 87 patients 60 were treated conservatively and 27 were operated upon Of the 60 patients treated by conservative methods 18 had fractures graded as Type I and 42 as Type II and Type III In Type I he found excellent or good results in 72 per cent in Type II in 30 per cent and in Type III in 11 per cent Twenty seven patients with fractures graded as Type II and III were operated upon In patients with Type II fractures he found excellent results in 6 patients good in 2 fair in 2 and poor in none In patients with Type III fractures he found excellent results in 5 good in 4 fair in 3 and poor in 5 Waller recommended open treatment in posterior acetabular fractures of Type II and III and he stated that Type I fractures are the only posterior acetabular fractures suited to closed treatment

Rowe & Lowell (1961) collected 93 patients with fracture-dislocation of the hip Seventeen of these had fracture of the posterior rim of the acetabulum Six of these 17 patients were treated conservatively and 11 operatively Three of the conservatively treated patients had excellent or good result 3 poor Eight of the operatively treated patients had excellent or good result 3 poor These authors recommend open treatment when there is a large displaced posterior acetabular fragment that must be reduced and fixed to restore stability of the joint or when displacement of a bone fragment is associated with sciatic nerve pressure or injury According to these authors closed treatment is satisfactory when the fragments are small and their reduction and fixation are not necessary to restore stability of the hip joint

Nerubay et al (1973) gave an account of the Tel Aviv Clinic cases between 1950 and 1969 During this period the authors collected 107 patients with 111 acetabular fractures where follow-up was available in 85 patients with 89 fractures Thirty six of these were posterior fractures and the mean time for follow up was 6 years Twenty nine of these 36 patients were treated conservatively and they found excellent or good results in 80 per cent and fair or poor in 20 per cent Only 7 patients were operated upon and the results were good in one fair in

pressed by the tendency of displaced and centrally dislocated hips treated by closed means to establish a satisfactory pseudo acetabulum after destruction and medial displacement of the inner acetabular wall

In the present investigation only 5 patients were operated upon They all had in common a severe central dislocation of the femoral head with fracture of the superior dome

Treatment of posterior acetabular fractures A review of literature

Posterior acetabular fractures were first described in 1824 by Sir Astley Cooper (Waller 1955) In 1855 Malgaigne described 12 cases and pointed out that a posterior acetabular fracture should be suspected when redislocation occurred after reduction of the hip

With time some advocated conservative treatment and others surgical In cases of posterior fracture dislocation there is, however, today a common agreement that reduction of the dislocated femoral head should be carried out as an emergency procedure (Stewart & Milford 1954, Waller 1955, Rowe & Lowell 1961, Lehtonen 1968, Epstein 1974, Stewart et al 1975)

Campbell (1936) collected 80 cases of posterior dislocation of the hip Of these 30 were combined with posterior acetabular fractures He divided his posterior fractures into three groups depending on the degree of posterior dislocation of the femoral head Nine could be traced and followed up, all treated conservatively and all but one showed excellent results The author pointed out that all these fractures did well if they were treated with early reduction of the dislocation and immobilization in bed with traction for 6 weeks

Funsten et al (1938) reported on 20 patients with traumatic dislocation of the hip In 9 of these the lesion was combined with a posterior fracture of the acetabulum According to the nature of the trauma Funsten et al gave these injuries the name "dash board dislocations" A follow up of 8 patients was carried out after 3 years All were treated conservatively and the result was good in 4, fair in 2 and poor in 2

In a series of 101 traumatic dislocations of the hip Armstrong (1948) described 50 patients in 43 of whom the dislocation of the femoral head was combined with a fracture of the posterior part of the acetabulum Fifteen of these were followed up after 3-4 years All but one patient were treated conservatively He found complete recovery in 63 per cent of these patients He stated that fractures of the posterior acetabulum with displacement of marginal fragments are usually corrected by manipulative reduction or by traction

Urist (1948) described 23 patients with fracture-dislocation of the hip Eighteen had fracture of the posterior superior part of the acetabulum and 13 were adequately followed up Eleven of these were operated upon and 2 were treated conservatively by traction Of the patients treated by surgery 5 had excellent or good results 3 fair and 3 poor Both patients treated by immobilization in bed and traction had poor results He stated that minor fractures of the posterior acetabular rim could be treated by conservative methods In cases in which a significant posterior acetabular fragment remained displaced after reduction of the femoral head the final result was only fair or poor on account of degenerative changes in the hip joint He recommended that posterior rim fractures with displacement of the fragment should be treated by open reduction and internal fixation

Stewart & Milford (1954) collected 193 patients with fracture-dislocations of the hip over a 30 year period Adequate follow up was made in 123 patients Of these 96 had posterior fractures These authors made a classification of posterior fracture-dislocation into four grades where Grade I was a posterior dislocation of the femoral head with no or only a slight fracture of the posterior rim without consequence and Grade IV was a posterior dislocation of the femoral head with a fracture of the femoral neck Posterior dislocation of the femoral head with a large single fragment or a comminute fracture of the posterior acetabular rim (Grade II and III respectively) accounted for 57 patients Fourty two of these were treated conservatively Sixteen were reported with excellent or good results 26 with fair or poor results Fifteen patients were treated surgically Six had excellent or good results and 9 had fair or poor results Mean time for follow up was 7 years These authors stress the importance of early treatment and advised open procedures only when closed reduction failed when the joint was unstable after closed reduction of the femoral head and when at radiologic examination loose fragments were found in the joint

Waller (1955) gave an account of 106 patients with posterior acetabular fractures collected over a 10 year period Follow up examinations were available in 87 patients with a mean time for follow up for 3 years and 11 months Of the 87 patients 60 were treated conservatively and 27 were operated upon Of the 60 patients treated by conservative methods 18 had fractures graded as Type I and 42 as Type II and Type III In Type I he found excellent or good results in 72 per cent in Type II in 30 per cent and in Type III in 11 per cent Twenty seven patients with fractures graded as Type II and III were operated upon In patients with Type II fractures he found excellent results in 6 patients good in 2 fair in 2 and poor in none In patients with Type III fractures he found excellent results in 5 good in 4 fair in 3 and poor in 5 Waller recommended open treatment in posterior acetabular fractures of Type II and III and he stated that Type I fractures are the only posterior acetabular fractures suited to closed treatment

Rowe & Lowell (1961) collected 93 patients with fracture-dislocation of the hip Seventeen of these had fracture of the posterior rim of the acetabulum Six of these 17 patients were treated conservatively and 11 operatively Three of the conservatively treated patients had excellent or good result 3 poor Eight of the operatively treated patients had excellent or good result 3 poor These authors recommend open treatment when there is a large displaced posterior acetabular fragment that must be reduced and fixed to restore stability of the joint or when displacement of a bone fragment is associated with sciatic nerve pressure or injury According to these authors closed treatment is satisfactory when the fragments are small and their reduction and fixation are not necessary to restore stability of the hip joint

Nerubay et al (1973) gave an account of the Tel Aviv Clinic cases between 1950 and 1969 During this period the authors collected 107 patients with 111 acetabular fractures where follow up was available in 85 patients with 89 fractures Thirty six of these were posterior fractures and the mean time for follow up was 6 years Twenty nine of these 36 patients were treated conservatively and they found excellent or good results in 80 per cent and fair or poor in 20 per cent Only 7 patients were operated upon and the results were good in one fair in

pressed by the tendency of displaced and centrally *dislocated hips* treated by closed means to establish a satisfactory pseudo acetabulum after destruction and medial displacement of the inner acetabular wall

In the present investigation only 5 patients were operated upon They all had in common a severe central dislocation of the femoral head with fracture of the superior dome

Treatment of posterior acetabular fractures A review of literature

Posterior acetabular fractures were first described in 1824 by Sir Astley Cooper (Waller 1955) In 1855 Malgaigne described 12 cases and pointed out that a posterior acetabular fracture should be suspected when redislocation occurred after reduction of the hip

With time some advocated conservative treatment and others surgical In cases of posterior fracture-dislocation there is, however, today a common agreement that reduction of the dislocated *femoral head should* be carried out as an emergency procedure (Stewart & Milford 1954, Waller 1955, Rowe & Lowell 1961, *Lehtonen 1968, Epstein 1974, Stewart et al 1975*)

Campbell (1936) collected 80 cases of posterior dislocation of the hip Of these 30 were combined with posterior acetabular fractures. He divided his posterior fractures into three groups depending on the degree of posterior dislocation of the femoral head Nine could be traced and followed up, all treated conservatively and all but one showed excellent results The author pointed out that all these fractures did well if they were treated with early reduction of the dislocation and immobilization in bed with traction for 6 weeks

Funsten et al (1938) reported on 20 patients with traumatic dislocation of the hip In 9 of these the lesion was combined with a posterior fracture of the acetabulum According to the nature of the trauma Funsten et al gave these injuries the name "dash board dislocations" A follow up of 8 patients was carried out after 3 years All were treated conservatively and the result was good in 4, fair in 2 and poor in 2

In a series of 101 traumatic dislocations of the hip Armstrong (1948) described 50 patients in 43 of whom the dislocation of the femoral head was combined with a fracture of the posterior part of the acetabulum Fifteen of these were followed up after 3-4 years All but one patient were treated conservatively He found complete recovery in 63 per cent of these patients *He stated that fractures of the posterior acetabulum with displacement* of marginal fragments are usually corrected by manipulative reduction or by traction

Urist (1948) described 23 patients with fracture-dislocation of the hip Eighteen had fracture of the posterior superior part of the acetabulum and 13 were adequately followed up Eleven of these were operated upon and 2 were treated conservatively by traction Of the patients treated by surgery 5 had excellent or good results, 3 fair and 3 poor Both patients treated by immobilization in bed and traction had poor results He stated that minor fractures of the posterior acetabular rim could be treated by conservative methods In cases in which a *significant posterior* acetabular fragment remained displaced after reduction of the femoral head the final result was only fair or poor on account of degenerative changes in the hip joint He recommended that posterior rim fractures with displacement of the fragment should be treated by open reduction and internal fixation

2 and poor in 4 Thus these authors reported good results with conservative treatment and recommend open treatment only for fractures that could not be reduced conservatively for fractures that remained unstabled after closed reduction of the femoral head and in lesions of the sciatic nerve by compression of the femoral head or bony fragments without recovery for 1 2 weeks

Solheim & Skrede (1973) presented a material of 95 patients with fracture of the aceta bulum Sixty six of these were followed up Fifty two were central acetabular fractures and 14 posterior acetabular fractures Twelve of the 14 patients with posterior fractures were operated upon with good results in 60 per cent Only 2 patients were treated conservatively one was given good result and one poor They recommended open treatment in all posterior acetabular fractures with dislocation of the acetabular fragment

Epstein (1974) gave an account of 242 posterior fracture-dislocations of the hip Twohun dredandthree belonged to Type II IV in the classification described on page 17 Ninety five patients were treated conservatively with closed reduction of the femoral head followed by immobilization in bed with or without traction Sixty one were treated with closed reduction of the femoral head followed by open fixation of the acetabular fragment and 47 were treat ed by primary open reduction of the femoral head and osteosynthesis of the acetabular frag ment(s) Satisfactory results were obtained in 14 per cent in the first group 44 per cent in the second group and 63 per cent in the third group From this series he concluded that early primary open reduction with removal of all loose fragments of bone and cartilage and resto ration of stability by internal fixation of the fracture of the acetabular rim offers the best prognosis in delaying the appearance of posttraumatic osteoarthrosis and to minimize its severity

On materials varying in size conservative treatment has been suggested irrespective of size and displacement of fragment and good results have been registered in 60 to 80 per cent (Bray 1962 Nicoll 1966) The mode of treatment has varied somewhat and in some cases traction is advocated in others immobilization in bed only

Surgical treatment has been suggested by Lehtonen (1968) Judet Judet & Letournel (1964) Johansson & Olerud (1971)

In Table 10 a summary of reported results of conservative and surgical treatment of pos terior acetabular fractures is presented

Present investigation (Tables 11 and 12)

Conservative treatment (19 patients)

The Type I fracture was treated with immobilization in bed without traction Time for im mobilization was 1 2 weeks Fifteen fractures of Type II and III were treated conservatively Of these 9 were immobilized in bed without traction the remaining 6 being treated with traction through the tibial tuberosity In 9 patients the fragment still remained dislocated af ter reduction of the femoral head Three of these were treated with traction and 6 were im mobilized in bed without traction There was no redislocation of the femoral head in any of the patients Times for immobilization and hospital stay are presented in Table 12

Summary on diagnosis and treatment of acetabular fractures

In summary there is agreement among most surgeons who treat fractures of the acetabulum on the following

1 For a detailed analysis of acetabular fractures the radiologic examination should include several projections of the joint
2 When the femoral head is dislocated posteriorly acute reduction should be performed
3 A large posterior acetabular fragment associated with instability requires open reduction and fixation of the acetabular fragment
4 The presence of a bone fragment in the hip joint blocking the reduction of a posteriorly dislocated femoral head is an indication for open reduction
5 A sciatic nerve palsy in combination with a posteriorly dislocated acetabular fragment requires early surgical exploration

The principle point of disagreement concerns the management of central acetabular fractures with displacement of fragments and central dislocation of the femoral head

Table 11 *Type and treatment of 39 posterior acetabular fractures*

Type of fracture	No of patients	
	Treated conservatively	Treated surgically
Type I	4	
Type II	5	10
Type III	10	10
Total	19	20

Type of fracture	Treated conservatively		Treated surgically	
	Immobilization (weeks)	Hospital stay (weeks)	Immobilization (weeks)	Hospital stay (weeks)
Type I	1 2	2–3		
Type II	3–4	4	4 5	7 8
Type III	4–5	7	5–6	8 9

Surgical treatment (20 patients)

In this material 20 patients with Type II and III fractures were operated upon The indication for operation in 15 patients was a remaining large displacement of one or several posterior fragments after reduction of the femoral head Three patients were operated upon because of impossibility to reduce the femoral head one patient because of redislocation of the femoral head after reduction and one patient because of sciatic nerve involvement with acute peroneal paresis

Sixteen patients were operated upon within 1 week one after 2 weeks one after 3 weeks and 2 after 4 weeks Various types of operative fixation were employed (Palmer s pin screw and cerclage)

Twelve of the patients operated upon were immobilized postoperatively in bed without traction 7 were put into traction and one had a plaster of Paris Times for immobilization and hospital stay are presented in Table 12

Table 13 *Type and treatment of 66 central acetabular fractures (Follow-up series)*

Type of fracture	No of patients	
	Treated conservatively	Treated surgically
Central fracture without central dislocation of the femoral head		
Without displacement of the acetabular fragments	13

Total	17	18

Time of follow-up

The time of follow-up varied from 1 12 years with a mean time of 6 1 years The distribution of the material according to the time of follow up was

9 – 12 years	25 patients
7 – 9 "	19 "
5 7 "	17 "
3 – 5 "	14 "
1 – 3 "	25 "

Chapter 3

A FOLLOW-UP STUDY OF 100 PATIENTS

Material

A follow-up of acetabular fractures treated during 1963-1973 was carried out from April 1974 to January 1975. Of the original 123 patients with 124 fractures the follow up comprised 100 patients representing 101 fractures. Twenty of the patients had died. Two were not accessible to any verbal or functional inquiry. One patient could not be traced

Of the 100 followed up patients 35 were women and 65 were men

The mean age for the whole material at follow-up was 45 years, for women 47 years and for the men 43 years

In Tables 13 and 14 the classification is presented of central and posterior fractures at follow-up

Deceased patients

Three patients died in connection with the injury, one as an immediate consequence to the accident, one after 8 days in pneumonia and one after 2 months in myocardial infarction Seventeen patients died of various causes unrelated to the injury 1-7 years after the accident

Mode of follow-up

Ninety five patients were questioned and examined by myself One patient was examined by another orthopaedic surgeon Three patients refused examination and one lived abroad. These 4 patients replied to a written questionnaire.

Three patients, who had a hip arthroplasty or hip fusion performed at a later date as a reconstructive procedure, were given a final clinical and radiologic rating for their hips prior to this later operation (One patient with a central fracture with severe central dislocation of the femoral head was operated upon after 3 years with a Smith Petersen cup One patient with a posterior fracture-dislocation of Type III treated surgically was operated upon with an arthrodesis 2 years after injury One patient with a posterior fracture-dislocation of Type II combined with a fracture of the femoral head had a Moore prosthesis implanted at the time of injury and after 2 years a Girdlestone procedure was performed)

Chapter 3

A FOLLOW-UP STUDY OF 100 PATIENTS

Material

A follow-up of acetabular fractures treated during 1963-1973 was carried out from April 1974 to January 1975. Of the original 123 patients with 124 fractures the follow-up comprised 100 patients representing 101 fractures. Twenty of the patients had died. Two were not accessible to any verbal or functional inquiry. One patient could not be traced.

Of the 100 followed-up patients 35 were women and 65 were men.

The mean age for the whole material at follow-up was 45 years, for women 47 years and for the men 43 years.

In Tables 13 and 14 the classification is presented of central and posterior fractures at follow-up.

Deceased patients

Three patients died in connection with the injury, one as an immediate consequence to the accident, one after 8 days in pneumonia and one after 2 months in myocardial infarction. Seventeen patients died of various causes unrelated to the injury 1-7 years after the accident.

Mode of follow-up

Ninety-five patients were questioned and examined by myself. One patient was examined by another orthopaedic surgeon. Three patients refused examination and one lived abroad. These 4 patients replied to a written questionnaire.

Three patients, who had a hip arthroplasty or hip fusion performed at a later date as a reconstructive procedure, were given a final clinical and radiologic rating for their hips prior to this later operation. (One patient with a central fracture with severe central dislocation of the femoral head was operated upon after 3 years with a Smith-Petersen cup. One patient with a posterior fracture-dislocation of Type III treated surgically was operated upon with an arthrodesis 2 years after injury. One patient with a posterior fracture-dislocation of Type II combined with a fracture of the femoral head had a Moore prosthesis implanted at the time of injury and after 2 years a Girdlestone procedure was performed.)

fied by Charnley (1972), has been used (Table 15)

The results of the follow up are presented in Tables 16-28

Pain

A summarizing presentation for all fractures is made in Table 16

Central fractures (66 patients)

Thirty patients had a *central fracture without central dislocation of the femoral head* (Table 17) The results concerning pain for this type of fracture were very satisfactory Twenty six patients (87 per cent) had no or only slight or intermittent pain Mean value was 5 6 points On comparison between patients with and without displacement of the acetabular fragments it is surprising to see that patients with displacement had better results than those without displacement of the acetabular fragments

A *mild to moderate central dislocation of the femoral head* was present in 18 patients (Table 18) Nine patients had no or only slight or intermittent pain and 4 had pain only after some activity (72 per cent) Mean value was 4 5 points The superior dome was intact in 11 patients and fractured in 7 Pain was less pronounced in patients with the superior dome intact (4 7 points) than in those with the superior dome fractured (4 1 points)

Thirteen patients with a *severe central dislocation of the femoral head were treated conservatively* (Table 19) Six patients had no pain and 2 pain only after some activity (61 per cent) Mean value was 4 5 points The superior dome was intact in 4 patients and 3 of these had no pain and one had pain only after some activity (5 5 points) In 9 patients the superior dome was fractured and the mean value for these patients was 4 0 points

Five patients with a *severe central dislocation of the femoral head were treated surgically* (Table 19) In all patients the superior dome was fractured and the mean value for pain was 3 6 points

Table 17 *Results concerning pain and walking in central fractures without central dislocation of the femoral head (30 fractures in 30 patients)*

Pain Points	Without dislocation of acetabular fragments	With dislocation of acetabular fragments	Walking Points	Without dislocation of acetabular fragments	With dislocation of acetabular fragments

6	9	15	6	10	15
	13	17		13	17
Mean value	5 2	5 9		5 3	5 9

Results

Assessment of results

It has become apparent from the literature that the assessment of results varies considerably due to the type of evaluation used (Anderson 1972) To minimize the examiner's subjective opinion and also to make an attempt to cover as many functional activities as possible in an objective way a numerical system suggested by d'Aubigné & Postel (1954), later modi-

Table 15. *Assessment table*

Points	Pain	Walking	Total motion (degrees)
1	Severe, spontaneous	Bedridden or few yards Two sticks or crutches	0–30
2	Severe on attempting to walk. Prevents all activity	Time and distance very limited with or without sticks	31–60
3	Pain tolerable. Permitting limited activity	Limited with one stick (less than 1 hour). Difficult without stick. Able to stand long periods	61–100
4	Pain only after some activity, disappears quickly at rest	Long distances with one stick Limited without a stick	101–160
5	Slight or intermittent pain on starting to walk but getting less with normal activity	No stick but a limp	161–210
6	No pain	Normal	211–

	4	9	5		4	9	5
Mean value	5 5	4 0	3 6		6 0	4 1	5 2

Correlation between results concerning pain in patients with good and less satisfactory reduction of the femoral head following conservative treatment (Table 20)

A mild to moderate or severe central dislocation of the femoral head was present in 31 of the 61 conservatively treated patients It was mild to moderate in 18 and severe in 13 The superior dome was intact in 15 of the 31 patients and fractured in 16

In the 15 patients with the superior dome intact a good reduction of the femoral head was achieved in 6 patients In the remaining 9 the reduction was less satisfactory The pain recorded for the reduced cases was 4 5 points and for the others 5 2 points

Walking

A summarizing presentation for all fractures is made in Table 22

Central fractures (66 patients)

Central fractures without central dislocation of the femoral head (Table 17) Twenty five of 30 patients had normal walking (80 per cent) The mean value was 5 6 points

A mild to moderate central dislocation of the femoral head was present in 18 patients and 10 of these had normal walking (Table 18). The mean value was 5 2 points. Whether the superior dome was fractured or not did not appear to influence the walking capacity in these patients.

Of the 13 patients with *severe central dislocation of the femoral head treated conservatively* 7 had a normal walking (Table 19) An interesting observation was made in the 4 patients in whom the superior dome was intact The grading was 6 in all In those 9 patients who had the superior dome fractured the result was graded as 4 1

In those 5 patients with *severe central dislocation of the femoral head treated surgically* the mean value was 5 2 points (Table 19)

Correlation between results concerning walking in patients with good and less satisfactory reduction of the femoral head following conservative treatment (Table 20)

Of 16 patients with varying degree of central dislocation of the femoral head and the superior dome fractured a good reduction could be achieved in 8 These patients had a better grading (5 4 points) than those 8 patients in whom a less satisfactory reduction was obtained (3 8 points) A good reduction in 6 of those 15 patients who had the superior dome intact did also result in better walking than for those with less satisfactory reduction (5 8 versus 5 2 points)

Table 22 *Results concerning walking (101 fractures in 100 patients)*

Walking	Points	Central fractures	Posterior fractures	Total
Bedridden or few yards. Two sticks or crutches	1			
Time and distance very limited with or without sticks	2	6	3	9
Limited with one stick (less than 1 hour) Difficult without stick Able to stand long periods	3	2	3	5
Long distances with one stick Limited without a stick	4	1	2	3
No stick but a limp	5	14	2	16
Normal	6	43	25	68
		66	35	101
Mean value		5 3	5 2	5,3

On judging the influence of the degree of reduction on the degree of pain in the 16 patients with the superior dome fractured no difference could be found between those with a good reduction and those with a less satisfactory reduction (4.1 versus 4 0 points).

Posterior fractures (35 patients)

The intensity of pain in posterior fractures could be related to the type of fracture (Table 21).

Only 3 patients had a *Type I-fracture*, and all 3 were free from pain

Type II-fracture was present in 15 patients. Ten patients had no or only slight or intermittent pain and 3 had pain only after some activity. The mean value was 5.2 points. Those patients treated conservatively had better results than those treated surgically (5 4 versus 4 9 points).

Seventeen patients had a *Type III-fracture*. Nine patients were treated conservatively and 8 surgically. The result concerning pain was 4 2 points in those treated conservatively and 4 6 in those treated surgically.

In 8 patients with Type II- and III-fractures, conservatively treated, the acetabular fragment remained dislocated after reduction of the femoral head. The mean value for these patients was 4 6 points.

Table 21 *Results concerning pain in posterior fractures (35 fractures in 35 patients)*

Points	Type I	Type II		Type III		Type II and III
	Treated conservatively	Treated conservatively	Treated surgically	Treated conservatively	Treated surgically	Treated conservatively with the fragment remained dislocated

5	–	1		1	1	–
6	3	3	6	2	4	3
	3	5	10	9	8	8
Mean value	6,0	5,4	4,9	4,2	4,6	4,6

Walking

A summarizing presentation for all fractures is made in Table 22.

Central fractures (66 patients)

Central fractures without central dislocation of the femoral head (Table 17). Twenty-five of 30 patients had normal walking (80 per cent). The mean value was 5 6 points.

A *mild to moderate central dislocation of the femoral head* was present in 18 patients and 10 of these had normal walking (Table 18). The mean value was 5 2 points. Whether the superior dome was fractured or not did not appear to influence the walking capacity in these patients

Of the 13 patients with *severe central dislocation of the femoral head treated conservatively* 7 had a normal walking (Table 19) An interesting observation was made in the 4 patients in whom the superior dome was intact. The grading was 6 in all In those 9 patients who had the superior dome fractured the result was graded as 4 1

In those 5 patients with *severe central dislocation of the femoral head treated surgically* the mean value was 5 2 points (Table 19)

Correlation between results concerning walking in patients with good and less satisfactory reduction of the femoral head following conservative treatment (Table 20)

Of 16 patients with varying degree of central dislocation of the femoral head and the superior dome fractured a good reduction could be achieved in 8 These patients had a better grading (5 4 points) than those 8 patients in whom a less satisfactory reduction was obtained (3 8 points) A good reduction in 6 of those 15 patients who had the superior dome intact did also result in better walking than for those with less satisfactory reduction (5.8 versus 5 2 points)

Table 22 *Results concerning walking (101 fractures in 100 patients)*

Walking	Points	Central fractures	Posterior fractures	Total
Bedridden or few yards Two sticks or crutches	1			–
Time and distance very limited with or without sticks	2	6	3	9
Limited with one stick (less than 1 hour). Difficult without stick Able to stand long periods	3	2	3	5
Long distances with one stick Limited without a stick	4	1	2	3
No stick but a limp	5	14	2	16
Normal	6	43	25	[illegible]
		66	35	101
Mean value		5,3	5,2	5,3

Posterior fractures (35 patients)

Results concerning walking in posterior fractures are given in Table 23.

All 3 patients with *Type I-fracture* had normal walking.

Twelve of the 15 patients who had a *Type II-fracture* had normal walking, including all 5 patients treated conservatively.

Of 17 patients with *Type III-fracture* 9 were treated conservatively and 8 surgically. The result in walking was 5.2 points in those treated without operation and 4.5 points in those operated upon.

In 8 patients with Type II- and III-fractures treated conservatively the acetabular fragments remained dislocated after reduction of the femoral head. Mean value for these patients was 5.6 points.

Total motion

The range of total motion (flexion, abduction, adduction, inward- and outward rotation) for each group is presented in Tables 24 and 25.

Central fractures (63 patients) (Table 24)

In 23 of the 29 patients with *central fractures without central dislocation of the femoral head* a normal range of motion was registered. The remaining 6 patients had decreased mobility which foremost concerned flexion and rotation.

In 7 of the 16 patients with *central fractures with mild to moderate dislocation of the femoral head* there was a restriction of motion, particularly concerning flexion and rotation The remaining 9 had a normal range of motion

211	6	2	5	6	6	4
		2	5	10	9	8
Mean value		6 0	6 0	5,2	5,4	5,0

In 8 of the central fractures with mild to moderate dislocation a good reduction was obtained of the femoral head and 5 of these patients had a normal range of motion Of the remaining 3 patients 2 had 5 points and one had 4 points.

Among those 8 patients in whom reduction had been less satisfactory 4 had 6 points, 2 had 5 points and 2 had 4 points.

In the 13 patients with *central fractures with severe central dislocation of the femoral head treated conservatively* only 3 had a normal range of motion. Four patients had 5 points, 5 had 4 points and one had 3 points. No difference in range of motion was registered between those with a good reduction (6 patients) and those with less satisfactory reduction of the femoral head (7 patients).

One of the 5 patients with *central fractures surgically treated* had normal motion. Four patients had a decreased range of motion (3-5 points)

Posterior fractures (34 patients) (Table 25)

Twenty-three patients had a normal range of motion. Three patients had 5 points, 6 had 4 points and 2 had 3 points.

Summary of results in pain and walking

To facilitate the comparison of the results of this investigation with the radiologic findings and with other reported results it has been found of practical value to make a summary of the results in groups of excellent, good, fair and poor.

The results concerning pain and walking have been summarized as follows

Excellent 12 points, Good 10-11 points, Fair 8-9 points, Poor 2-7 points

The results as graded above are presented in Tables 26 and 27

Seventy-three per cent of the whole material had excellent or good result, 12 per cent fair and 16 per cent poor

Results concerning total motion have been excluded from this summary A correlation between the results concerning pain and walking, and total motion has been made and is presented in Table 28. From this it can be seen that a close relationship exists

Central fractures (66 patients)

Central fractures without central dislocation of the femoral head (30 patients) Ninety per cent had excellent or good results Twenty three patients had excellent result, 4 good, 1 fair and 2 poor Those 3 patients with fair or poor results had all central fractures without displacement of the acetabular fragments

Central fractures with mild to moderate central dislocation of the femoral head (18 patients) Sixty-seven per cent had excellent or good results Five patients had excellent result, 7 good, 4 fair and 2 poor Eleven patients had the *superior dome intact*, the result was excellent in 3, good in 6, fair in 1, and poor in 1 Reduction of the femoral head has not influenced in the results in this group In 7 patients the *superior dome was fractured*, the result was excellent in 2, good in 1 fair in 3, and poor in 1 In those 4 patients with fair or poor result there was

Table 26 *Results concerning pain and walking graded in excellent to poor in 66 patients with central acetabular fractures*

	59	16	[illegible]	4	–	–	97

a good reduction of the femoral head in 2 and a less satisfactory reduction in 2

Central fractures with severe central dislocation of the femoral head treated conservatively (13 patients) Fifty four per cent had excellent or good result Five patients had excellent result, 2 good, 2 fair, and 4 poor In 4 patients the *superior dome was intact*, the result was excellent in 3, and good in 1 In 2 patients there was a good reduction of the femoral head and in 2 the reduction was less satisfactory In 9 patients the *superior dome was fractured*, the result was excellent in 2, good in 1, fair in 2, and poor in 4 In 4 patients there was a good reduction of the femoral head One of these had excellent result, 2 fair and 1 poor In 5 patients there was a less satisfactory reduction of the femoral head One of these had excellent result, 1 good and 3 poor

Of 31 patients treated conservatively with a mild to moderate or severe central dislocation of the femoral head the *superior dome was intact* in 15 Eighty seven per cent had excellent or good result and 13 per cent fair or poor Six patients had excellent result, 7 good 1 fair, and 1 poor In 6 patients there was a good reduction of the femoral head Any difference in the results between patients with good and less satisfactory reduction was not obtained

In 16 patients with a mild to moderate or severe central dislocation of the femoral head treated conservatively the *superior dome was fractured* Six of these patients had excellent or good result (38 per cent) and 10 fair or poor (62 per cent) Four had excellent result 2 good 5 fair, and 5 poor Good reduction of the femoral head was obtained in 8 patients Two of these had excellent result, 1 good 4 fair, and 1 poor

Central fractures with a severe central dislocation of the femoral head treated surgically (5 patients) One patient had good result and 4 fair

Posterior fractures (35 patients)

Type I (3 patients) All 3 patients had excellent result

Type II – treated conservatively (5 patients) Three patients had excellent result and 2 good In all the femoral head was dislocated posteriorly

Type II – treated surgically (10 patients) Six patients had excellent result, 1 good, 0 fair, and 3 poor In all patients the femoral head was dislocated posteriorly A poor result was recorded in the following 3 patients 1 A 74 year-old woman who was treated with acute reduction of the femoral head and put into traction After 4 weeks there was a redislocation posteriorly of the femoral head Open reduction of the femoral head and fixation of the acetabular fragment was performed 2 A 60 year-old man Closed reduction of the femoral head failed and after 3 days an open procedure was performed Because of fracture of the femoral head the patient was operated with a Moore prosthesis The posterior acetabular fragment was put into place and fixed with two pins After 6 months pain progressed to a degree which eventually made a Girdlestone procedure necessary 2 years after injury 3 A 77 year-old man who was treated with acute reduction of the femoral head After 3 days the joint was opened and the posterior acetabular fragment put into place and fixed with two pins

Type III – treated conservatively (9 patients) Two patients had excellent result 4 good, 1 fair, and 2 poor Seven patients had at the first radiologic examination a posterior dislocation of the femoral head and in 2 patients no posterior dislocation could be observed These 2 pa

tients had excellent and good result A poor result was recorded in the following 2 patients 1 A 40-year-old man The posterior dislocation of the femoral head was not noticed until after 2 months 2 A 50 year-old woman who was treated with traction through the tibial tuberosity for 3 weeks following acute reduction of the femoral head

Type III – treated surgically (8 patients) Four patients had excellent result 1 good 0 fair and 3 poor In all patients but one there was a posterior dislocation of the femoral head A poor result was recorded in the following 3 patients 1 A 58-year-old woman with a comminute fracture of the acetabulum She was operated upon acute with open reduction of the dislocated femoral head and fixation of a big posterior acetabular fragment with two pins In addition this patient had a central fracture and after the operation the femoral head was dislocated 10 mm medially She was postoperatively treated with traction through the tibial tuberosity for 6 weeks 2 A 47 year-old woman who was treated with acute closed reduction after 6 12 hours After 1 week she was operated upon and a big posterior acetabular fragment was put into place and fixed with two pins Postoperatively she was immobilized in bed for 7 weeks Two years after the injury she developed necrosis of the femoral head leading to arthrodesis 3 A 20 year-old man who was treated with acute closed reduction of the femoral head Because of redislocation he was operated after 8 days with open reduction of the femoral head and osteosynthesis of the posterior acetabular fragments

Of 32 patients with posterior acetabular fractures classified as Type II and III-fractures 14 were treated conservatively and 18 surgically Of those treated conservatively 79 per cent had excellent or good results and 21 per cent fair or poor Five patients had excellent result 6 good 1 fair and 2 poor Of those patients treated surgically 67 per cent had excellent or good result and 33 per cent poor Ten patients had excellent result 2 good 0 fair and 6 poor

There were poor results in 8 patients of whom 5 had unfavourable features i.e. redislocation of the femoral head delayed reduction of the femoral head never reduced dislocation of the femoral head and a central fracture in addition to the posterior

Time of onset of post-injury symptoms

Those patients who did not have 6 points for pain and walking were interrogated as to the time of onset of symptoms Eighty per cent maintained that their discomfort had developed at the accident and remained stationary ever since Eight per cent had a début after 1 2 years 2 per cent after 2-4 years and 10 per cent after 4 years

Working capacity

Central fractures (66 patients)

Central fractures without central dislocation of the femoral head (30 patients) Five patients were retired at the time of injury Four received sick compensation for other reasons Two had changed to lighter work One received sick compensation because of the hip injury One still received rehabilitation treatment (1 year follow up) Seventeen remained in their original work which for 9 was of the heavy type i e labour Two were house wifes and 6 had a lighter type of work

Central fractures with mild to moderate central dislocation of the femoral head (18 patients) Two patients were retired at the time of injury One received sick compensation due to additional injury (fracture of the tibia) Two received sick compensation because of hip discomfort Two had changed to lighter work Eleven remained in their original work, which in 5 was of the heavy type Six had a lighter type of work

Central fractures with severe central dislocation of the femoral head treated conservatively (13 patients) Three patients were retired at the time of injury One had changed to lighter work Two received sick compensation because of hip discomfort Seven returned to their original work which for one patient was of the heavy type Two were house wifes and 4 had a lighter type of work

Central fractures with severe central dislocation of the femoral head treated surgically (5 patients) One patient received sick compensation because of hip discomfort Two had changed to lighter work One was still at school (could not partake in physical exercise) One returned to original work as a heavy worker

Posterior fractures (35 patients)

Type I (3 patients) All 3 patients returned to their original work One was a heavy worker and 2 had a lighter type of work

Type II – treated conservatively (5 patients) One patient had changed to a lighter work The remaining 4 returned to their original work Of these one was a heavy worker and 3 had a lighter type of work

Type II – treated surgically (10 patients) One patient was retired at the time of injury One was still in school (had done his military service and could partake in physical exercise) One received sick compensation due to hip discomfort One had changed to lighter work Six remained in their original work which for 4 was of the heavy type Two had a lighter type of work

Type III – treated conservatively (9 patients) One patient was retired at the time of injury One received sick compensation due to hip discomfort Two had changed to lighter work Five remained in their original work Of these one was a heavy worker and 4 had a lighter type of work

Type III – treated surgically (8 patients) Two patients had sick compensation due to hip discomfort One had changed to lighter work Five remained in their original work which for 2 was of a heavy type One patient was a house wife and 2 had a lighter type of work

RADIOLOGIC FOLLOW-UP STUDY

Degenerative changes

Osteoarthrosis and avascular necrosis of the femoral head are late complications which are considered to yield poor results In Table 29 a summary of late complications as reported in the literature is presented

Osteoarthrosis

Of 1152 reported patients (Table 29) osteoarthrosis was found in 6 6 to 62 per cent.

Avascular necrosis of the femoral head

Avascular necrosis of the femoral head developed in 4 to 30 per cent (Table 29)

As regards posterior fractures Stewart & Milford (1954) and *Brav (1962) noted that this* complication occurred less frequently in fractures treated by conservative methods However, Waller (1955) presented a higher percentage of avascular necrosis in patients not being operated upon

Most authors stress the importance of early reduction of the posteriorly dislocated femoral head in order to minimize the frequency of necrosis and arthrotic changes (Stewart & Milford 1954, 1975 Brav 1962, Epstein 1974) When reduction was delayed for more than 12 hours the incidence of avascular necrosis became three times as frequent (Brav 1962)

In a material of 242 patients with posterior dislocations and fracture-dislocations Epstein (1974) noted 18 per cent avascular necrosis In those patients treated with primary open reduction of the femoral head the frequency of avascular necrosis was 5.3 per cent and in the remainder 21 per cent

Ectopic ossification

Ectopic ossification occurs to a varying extent after acetabular fractures This has particularly been the case when surgical treatment has been carried out Stewart & Milford (1954) noted 2 2 per cent in their patients treated conservatively Waller (1955) *found 14 cases in* 106 posterior acetabular fractures (13 1 per cent) Ten of these cases belonged to the operated category and 4 to the group treated conservatively Brav (1962) reported a frequency of 13 2 per cent and Judet & Letournel (1974) a frequency of 20 2 per cent

As a rule ectopic ossification has not been accompanied by any symptoms and no special treatment has been recommended

Central fractures with mild to moderate central dislocation of the femoral head (18 patients) Two patients were retired at the time of injury One received sick compensation due to additional injury (fracture of the tibia) Two received sick compensation because of hip discomfort Two had changed to lighter work Eleven remained in their original work which in 5 was of the heavy type Six had a lighter type of work

Central fractures with severe central dislocation of the femoral head treated conservatively (13 patients) Three patients were retired at the time of injury One had changed to lighter work Two received sick compensation because of hip discomfort Seven returned to their original work which for one patient was of the heavy type Two were house wifes and 4 had a lighter type of work

Central fractures with severe central dislocation of the femoral head treated surgically (5 patients) One patient received sick compensation because of hip discomfort Two had changed to lighter work One was still at school (could not partake in physical exercise) One returned to original work as a heavy worker

Posterior fractures (35 patients)

Type I (3 patients) All 3 patients returned to their original work One was a heavy worker and 2 had a lighter type of work

Type II – treated conservatively (5 patients) One patient had changed to a lighter work The remaining 4 returned to their original work Of these one was a heavy worker and 3 had a lighter type of work

Type II – treated surgically (10 patients) One patient was retired at the time of injury One was still in school (had done his military service and could partake in physical exercise) One received sick compensation due to hip discomfort One had changed to lighter work Six remained in their original work which for 4 was of the heavy type Two had a lighter type of work

Type III – treated conservatively (9 patients) One patient was retired at the time of injury One received sick compensation due to hip discomfort Two had changed to lighter work Five remained in their original work Of these one was a heavy worker and 4 had a lighter type of work

Type III – treated surgically (8 patients) Two patients had sick compensation due to hip discomfort One had changed to lighter work Five remained in their original work which for 2 was of a heavy type One patient was a house wife and 2 had a lighter type of work

Present investigation

At the clinical follow up a radiologic study was also performed The purpose of the radiologic examination was to determine the frequency and the degree of possible degenerative changes of the fractured joint and the frequency of ectopic ossification

Examination technique

In 83 patients both hips were examined in the supine position, but no examination with weight-bearing on the hip was carried out

An AP view was taken with the thigh slightly inward rotated and with the centre of the beam directed to the femoral head Furthermore, a projection according to Cleave – also called Lauenstein's projection – was made This implies an AP view of the acetabulum with the thigh abducted 45° and with an external rotation of about 60° In patients with a decreased mobility of the hip joint, this projection was made in the utmost position the patient could attain In Cleave s projection the acetabulum appears mainly the same as in the AP view projection but the femoral head becomes externally rotated thus visualizing anterior and posterior parts of the femoral head

In 10 patients there were some diagnostic doubts whether degenerative lesions were present or not These patients were also examined under weight-bearing conditions, i e in a standing position An AP view of each hip was taken as well as an "en face" view An "en face" view implies a semilateral projection of the hip where the centre of the beam was directed transversally through the pelvis and centralized through a point slightly posterior to the opposite femoral head The object of that particular projection was to obtain a beam direction parallel to other parts of the joint space than those demonstrated on the AP projection The "en face" projection demonstrates parts of the anterior joint space the central joint space, and parts of the posterior joint space In order to get an ideal positioning of each hip fluoroscopy was utilized

All films obtained at the follow up study were studied together with all earlier films in order to make a complete review of each case

Definitions and classifications

Osteoarthrosis

The earliest radiologically definable stage of osteoarthrosis of the hip is narrowing of the joint space The width of the joint space reflects the thickness of the articular cartilage In this study the joint space was interpreted as abnormally decreased if it was more than 1 millimeter narrower than the contralateral normal side

The presence of osteophytes without a concomitant narrowing of the joint space was accordingly excluded as a single criterion of the diagnosis of osteoarthrosis of the hip These considerations have also been suggested by Danielsson (1964) and Ahlback (1971)

Table 29 *Frequency of osteoarthrosis and necrosis of the femoral head and ectopic ossification reported in the literature in patients with fracture-dislocation of the hip*

Author	No. of pat followed up	Mean time of follow-up-years	Type of fracture	Osteo-arthrosis per cent	Avascular Necrosis per cent	Ectopic ossification per cent
Stewart & Milford 1954	77	7,0	Posterior acetabular fractures	60	30 (17)	
			Central fractures	59	23	
Waller 1955	87	3,9	Posterior acetabular fractures	44,8 (50)	19,6 (26)	13,1☆

The figures within parenthesis represent the frequencies for patients treated conservatively.

☆ 14 of 106 patients

Present investigation

At the clinical follow up a radiologic study was also performed. The purpose of the radiologic examination was to determine the frequency and the degree of possible degenerative changes of the fractured joint and the frequency of ectopic ossification.

Examination technique

In 83 patients both hips were examined in the supine position, but no examination with weight-bearing on the hip was carried out.

An AP view was taken with the thigh slightly inward rotated and with the centre of the beam directed to the femoral head. Furthermore, a projection according to Cleave – also called Lauenstein's projection – was made. This implies an AP view of the acetabulum with the thigh abducted 45° and with an external rotation of about 60°. In patients with a decreased mobility of the hip joint, this projection was made in the utmost position the patient could attain. In Cleave's projection the acetabulum appears mainly the same as in the AP view projection but the femoral head becomes externally rotated, thus visualizing anterior and posterior parts of the femoral head.

In 10 patients there were some diagnostic doubts whether degenerative lesions were present or not. These patients were also examined under weight-bearing conditions, i.e. in a standing position. An AP view of each hip was taken as well as an "en face" view. An "en face" view implies a semilateral projection of the hip where the centre of the beam was directed transversally through the pelvis and centralized through a point slightly posterior to the opposite femoral head. The object of that particular projection was to obtain a beam direction parallel to other parts of the joint space than those demonstrated on the AP projection. The "en face" projection demonstrates parts of the anterior joint space, the central joint space, and parts of the posterior joint space. In order to get an ideal positioning of each hip, fluoroscopy was utilized.

All films obtained at the follow up study were studied together with all earlier films in order to make a complete review of each case.

Definitions and classifications

Osteoarthrosis

The earliest radiologically definable stage of osteoarthrosis of the hip is narrowing of the joint space. The width of the joint space reflects the thickness of the articular cartilage. In this study the joint space was interpreted as abnormally decreased if it was more than 1 millimeter narrower than the contralateral normal side.

The presence of osteophytes without a concomitant narrowing of the joint space was accordingly excluded as a single criterion of the diagnosis of osteoarthrosis of the hip. These considerations have also been suggested by Danielsson (1964) and Ahlback (1971).

In this study a two stage classification of osteoarthrosis was utilized:

Grade 1: Mild to moderate arthrosis

Slight to moderate narrowing of the joint space. None or only slight secondary changes of sclerosis and/or cyst formation in the acetabulum and/or the femoral head. No, slight or moderate formation of osteophytes.

Grade 2: Severe osteoarthrosis

Advanced or total obliteration of the joint space. Marked secondary changes of sclerosis, cyst formation and large osteophytes. The obliteration was considered advanced when the joint space was found to be less than 1 millimeter.

Avascular necrosis of the femoral head

The radiographic appearance of avascular necrosis is an archlike radiolucency which occurs parallell to the subchondral surface of the femoral head. Its presence alone, without any of the other characteristic features, was regarded good evidence of ischemic necrosis.

A narrow lip of sclerotic bone surrounds the radiolucent zone. At first, the joint space is normal, but later, when the necrotic ischemic bone collapses, the articular surface is flattened and the articular cartilage destroyed (Edeiken & Hodes 1975).

Material

Ninety-three patients with 94 acetabular fractures were examined radiologically. Of 100 patients followed up clinically, 6 could not be assessed by radiologic examination Four of these refused any clinical or radiologic examination and instead replied to a written questionnaire. Two patients could be examined clinically but refused radiologic examination.

Moreover one patient with a posterior fracture dislocation with damage to the femoral head has been excluded as the acute procedure following injury was an arthroplasty with a Moore prosthesis which after 2 years was removed and turned into a Girdlestone hip

Results

In 2 patients mild to moderate arthrotic changes were observed at the first radiologic examination

At the follow-up arthrotic changes were found in 37 out of 94 hips (39 per cent) The distribution of arthrotic changes within the different types of acetabular fractures is demonstrated in Table 30. The 37 patients who developed osteoarthrosis had a mean age of 46 years at the time of injury, 21 were men and 16 women. The mean time for follow-up of the 37 patients with osteoarthrotic changes was 5 years and 5 months. (The mean time for follow-up of the whole material was 6.1 years.)

There were 8 patients who developed necrosis of the femoral head in addition to arthrotic changes (Table 31) Five of these patients had a central fracture and 3 a posterior fracture of Type II or III in combination with a posterior dislocation of the femoral head.

Table 30 *Results of radiologic follow-up (osteoarthrosis) in comparison to clinical rating*

Type of fracture	Normal joint space				Grade I arthrosis				Grade II arthrosis				Total
	Excellent	Good	Fair	Poor	Excellent	Good	Fair	Poor	Excellent	Good	Fair	Poor	
Central fractures without central dislocation of the femoral head													
Without displacement of the acetabular fragments	9	1	1					1				1	13
With displacement of the acetabular fragments	12	3							1				16

In this study a two stage classification of osteoarthrosis was utilized

Grade 1 Mild to moderate arthrosis

Slight to moderate narrowing of the joint space None or only slight secondary changes of sclerosis and/or cyst formation in the acetabulum and/or the femoral head. No, slight or moderate formation of osteophytes

Grade 2 Severe osteoarthrosis

Advanced or total obliteration of the joint space Marked secondary changes of sclerosis, cyst formation and large osteophytes The obliteration was considered advanced when the joint space was found to be less than 1 millimeter

Avascular necrosis of the femoral head

The radiographic appearance of avascular necrosis is an archlike radiolucency which occurs parallell to the subchondral surface of the femoral head Its presence alone, without any of the other characteristic features, was regarded good evidence of ischemic necrosis

A narrow lip of sclerotic bone surrounds the radiolucent zone At first, the joint space is normal, but later, when the necrotic ischemic bone collapses, the articular surface is flattened and the articular cartilage destroyed (Edeiken & Hodes 1975)

Material

Ninety three patients with 94 acetabular fractures were examined radiologically Of 100 patients followed up clinically, 6 could not be assessed by radiologic examination Four of these refused any clinical or radiologic examination and instead replied to a written questionnaire Two patients could be examined clinically but refused radiologic examination

Moreover one patient with a posterior fracture dislocation with damage to the femoral head has been excluded as the acute procedure following injury was an arthroplasty with a Moore prosthesis which after 2 years was removed and turned into a Girdlestone hip

Results

In 2 patients mild to moderate arthrotic changes were observed at the first radiologic examination

At the follow up arthrotic changes were found in 37 out of 94 hips (39 per cent) The distribution of arthrotic changes within the different types of acetabular fractures is demonstrated in Table 30 The 37 patients who developed osteoarthrosis had a mean age of 46 years at the time of injury, 21 were men and 16 women The mean time for follow up of the 37 patients with osteoarthrotic changes was 5 years and 5 months (The mean time for follow up of the whole material was 6 1 years)

There were 8 patients who developed necrosis of the femoral head in addition to arthrotic changes (Table 31) Five of these patients had a central fracture and 3 a posterior fracture of Type II or III in combination with a posterior dislocation of the femoral head

Central fractures (61 patients)

Twenty three patients had radiologic evidence of osteoarthrosis (38 per cent) Eleven had mild [redacted] moderate arthrotic changes (Grade I) and 12 had severe arthrotic changes (Grade II) In addition 5 had necrosis of the femoral head

Central fractures without central dislocation of the femoral head (29 patients) Twenty-six patients had *no* signs of osteoarthrosis or avascular necrosis (90 per cent) Mild to moderate arthrotic changes were found in one patient and severe arthrotic changes in 2 These latter both had necrosis of the femoral head One of them, a 68 year-old woman, had sustained a minor acetabular fracture when falling on the same level After 2 1/2 years she developed necrosis of the femoral head (Fig 20) The other patient, a 66-year-old man, had sustained a central acetabular fracture with 10 millimeter medial dislocation of a fragment The radiologic examination at the time of injury showed mild to moderate osteoarthrosis and 9 months after injury the patient developed a severe osteoarthrosis and femoral head necrosis

At the time of injury there was a dislocation between the acetabular fragments exceeding 3 millimeter in 16 patients In all those patients the fracture gap had been filled in with bone and a congruent socket had developed (Fig 22)

Central fractures with mild to moderate central dislocation of the femoral head (16 patients) In 8 patients no signs of osteoarthrosis or femoral head necrosis could be detected (50 per cent) Six patients had mild to moderate and 2 severe arthrotic changes In one patient with severe arthrotic changes mild to moderate osteoarthrosis had been observed at the time of injury The other patient with severe osteoarthrosis had in addition necrosis of the femoral head

In 8 patients there was a good reduction of the femoral head Five of these had no arthrotic changes nor any femoral head necrosis and 3 had mild to moderate osteoarthrosis

In 8 patients there was less satisfactory reduction of the femoral head In 3 of these there were no signs of degenerative changes Of the remaining 5 3 had mild to moderate and 2 severe osteoarthrosis One of the latter developed necrosis of the femoral head

Central fractures with severe central dislocation of the femoral head treated conservatively (11 patients) Three patients had no signs of osteoarthrosis Two patients had mild to moderate and 6 had severe osteoarthrosis One of the patients with mild to moderate arthrotic changes and one of the 6 patients with severe arthrotic changes had femoral head necrosis

In 6 patients there was a good reduction of the femoral head In 3 of these no signs of osteoarthrosis or femoral head necrosis could be detected One had mild to moderate and 2 had severe arthrotic changes

In 5 patients a less satisfactory reduction was obtained All of these had osteoarthrotic changes one mild to moderate and 4 severe One of the patients sustained a pertrochanteric fracture [redacted] the time of injury He developed a severe osteoarthrosis which eventually was treated by an arthroplasty according to Smith Petersen

Central fractures with severe central dislocation of the femoral head treated surgically (5 patients) One patient had no signs of osteoarthrosis Two patients had mild to moderate and 2 had severe arthrotic changes

Table 31 *Avascular necrosis of the femoral head in 8 patients*

Type of fracture	No of patients	Time until reduction of the femoral head	Damage to the femoral head visible on original radiograph	Changes first visible on radiograph	Clinical rating
Central fractures without central dislocation of the femoral head					
Without displacement of the acetabular fragments	1	–	–	2 years 6 months	poor
With displacement of the acetabular fragments	1	–	–	9 months	excellent
Central fractures with mild to moderate central dislocation of the femoral head					
Superior dome intact					
Superior dome fractured	1	not reduced	–	7 months	poor
Central fractures with severe central dislocation of the femoral head					
Superior dome intact	1	not reduced	lateral superior part	12 months	excellent
Superior dome fractured treated conservatively	1	1 day	–	10 months	poor
Superior dome fractured treated surgically					
Posterior fractures					
Type I					
Type II treated surgically	1	< 12 hours Redislocation after 4 weeks	anterior part	1 year 6 months	poor
Type III treated surgically	2	1 < 12 hours	–	10 years 9 months	poor
		2 < 12 hours	medial ant. part	11 months	poor

Two deceased patients with a posterior fracture Type III operated upon could be examined 4 years after injury They both developed arthrosis Grade II and necrosis of the femoral head Time for reduction was within 12 hours and no damage to the femoral head could be observed at the time of injury for either of these patients. Changes were first visible on radiograph at 3 months

Type I (2 patients) Two patients with posterior fractures of this type were radiologically examined and none of them showed any sign of osteoarthrosis

Type II – treated conservatively (5 patients) Four patients had no signs of osteoarthrosis and one had mild to moderate arthrotic changes

Type II – treated surgically (9 patients) Five patients had a normal joint space without any radiologic signs of osteoarthrosis or femoral head necrosis Three patients had mild to moderate and one had severe arthrotic changes This patient also developed femoral head necrosis One patient had at the time of injury a fracture of the femoral head with a little fragment dislocated The fragment was removed and the dislocated posterior acetabular fragment was fixed with two pins This patient had at the time of follow up 11 years after the operation mild to moderate arthrosis

Type III – treated conservatively (9 patients) Six patients had no signs of osteoarthrosis 2 had mild to moderate and one had severe osteoarthrosis

Type III – treated surgically (8 patients) Two patients had no signs of osteoarthrosis, 3 had mild to moderate and 3 had severe osteoarthrosis Two of the latter developed a femoral head necrosis

Fourteen patients classified as Type II and III were treated conservatively and in 4 of these degenerative changes were observed (29 per cent) Seventeen patients classified as Type II and III were treated surgically Ten of these had osteoarthrotic changes (60 per cent) of which 3 had femoral head necrosis

*Thirty patients were not included in the radiologic follow-up study Only 6 of these had been radiologic*ally examined for more than 1 year following the injury They are specified as follows

One patient with a posterior acetabular fracture Type III combined with a posterior dislocation of the femoral head treated surgically was examined up to 2 years and 6 months after injury At the time of injury no damage of the femoral head was observed After 1 month ectopic ossification was noted and after 3 months necrosis of the femoral head developed and also a total destruction of the joint cartilage

One patient with a posterior fracture Type III treated surgically was examined up to 4 years and 2 months after injury He developed necrosis of the femoral head and ankylosis of the hip joint and ectopic ossification

One patient with a central fracture with severe central dislocation of the femoral head and fracture of the superior dome was examined up to 3 years and 9 months after injury A mild to moderate osteoarthrosis could then be observed This patient had been treated conservatively without traction

The other 3 patients had all central fractures without central dislocation of the femoral head and were examined up to 4 years after injury None of them showed any sign of osteoarthrosis or femoral head necrosis.

Correlation between clinical results and radiologic findings in 94 hips with acetabular fractures

In those 57 hip joints without radiologic signs of osteoarthrosis or femoral head necrosis the clinical results were excellent to good in 52 cases (91 per cent) Of the 47 patients with clinically excellent results 39 had no radiologic evidence of osteoarthrosis (83 per cent) (Table 33)

In 14 patients with mild to moderate or severe central dislocation of the femoral head treated conservatively a good reduction of the femoral head had been achieved There was no re dislocation centrally of the femoral head There seems to have been little influence on the centrally dislocated fragments by traction Further, it seems that in the healing procedure nature had filled in the space between the femoral head and the fragments and that a smooth congruent articulating surface had developed

In those 13 patients with mild to moderate or severe central dislocation of the femoral head treated conservatively, in whom less satisfactory reduction had been achieved a new "pseudo-acetabulum" or "false joint" between the two joint components was observed (Fig 25)

Correlation between osteoarthrotic changes and reduction of the femoral head

A correlation between arthrotic changes and reduction of the femoral head in 27 patients with mild to moderate or severe central dislocation of the femoral head treated conservatively is presented in Table 32 In 4 of 6 patients with good reduction of the femoral head and the superior dome intact there were no signs of osteoarthrotic changes In 5 of 6 patients with less satisfactory reduction of the femoral head and the superior dome fractured there were arthrotic changes, mild to moderate in one and severe in 4

In 13 patients the superior dome was intact Six of these had no signs of osteoarthrosis (46 per cent) Five patients had mild to moderate and 2 severe arthrotic changes (54 per cent)

In 14 patients the superior dome was fractured Five of these had no signs of osteoarthrosis (36 per cent) Three patients had mild to moderate and 6 severe arthrotic changes (64 per cent)

Posterior fractures (33 patients)

Fourteen patients had radiologic evidence of osteoarthrosis (42 per cent) Nine patients had mild to moderate and 5 severe arthrotic changes In addition 3 patients had necrosis of the femoral head

CASE REPORTS

Ectopic ossification

Of 99 patients radiologically examined for more than 1 year ectopic ossification was observed in 13 patients (Table 34). Two of these patients had been treated conservatively and 11 surgically. The changes usually developed 1-4 weeks after the injury and no special treatment was given.

Chapter 5

DISCUSSION

Since the earliest description of acetabular fractures with intrapelvic penetration of the femoral head by Callisen 1778 (Schroeder 1909) there has been many reports dealing with these fractures This injury was uncommon before the onset of serious automobile accidents. During the first 50 years of the 20th century trauma to the hip became more frequent due to the intensified motor traffic The hip lesion encountered in surgical practice exhibited new features typical of motor-car injuries, the damage as a rule being caused by stronger forces than before The most common traumatic mechanism producing *central* acetabular fractures is a blow to the trochanteric region and the injury is mostly sustained in connection with traffic accidents, being frequently found among pedestrians In this material the cause of injury was traffic accident in 45 patients Twenty nine of these were pedestrians hit by a car *Posterior* fractures are often the result of motor-car accidents The fracture and fracture-dislocation are frequently caused by a blow applied along the long axis of the femur The mechanism was so often an accompaniment of motor car accidents where the patient's knee struck against the dash-board that the dislocations and fracture-dislocations were given the name of dash-board dislocations (Funsten et al 1938) and dash-board fractures (Waller 1955). In the present material 29 of 39 posterior acetabular fractures were caused by motor-car accidents, the patient being either driver or passenger in the car

It is not until the last 20 years that larger series dealing with acetabular fractures have been published, making it possible to evaluate the results of different forms of treatment

However, fractures of the acetabulum are relatively rare and furthermore individual variations between fractures occur, making it difficult to arrive at a simple classification or to outline the management of these patients This absence of a uniform method of classification makes comparisons between materials almost impossible Methods of evaluating results vary greatly, and the radiologic criterias used when evaluating the joint following trauma are not uniform

Regarding the classification of *central* acetabular fractures some authors classify their fractures depending on the degree of central dislocation of the femoral head (Stewart & Milford 1954, Bohler 1954, Pearson & Hargadon 1962, Eichenholtz & Stark 1964, Lehtonen 1968). Others have found it more important to take account of the fracture lines and which part of the acetabulum that becomes involved (Knight & Smith 1958, Rowe & Lowell 1961, Judet, Judet & Letournel 1964)

This investigation included 30 patients, all treated conservatively Twenty-eight were immobilized in bed only and 2 were put into traction. Time for immobilization was 2 weeks Twenty seven of 30, i e. 90 per cent, had excellent or good result, which is well comparable with other reported results The results for patients with displacement of the acetabular fragment were even better than for those without displacement. All patients with fair or poor result had undisplaced fractures. Only 3 of 29 patients radiologically examined showed signs of osteoarthrosis and 2 of these had in addition a necrosis of the femoral head

It seems that acetabular fractures without central dislocation of the femoral head with or without displacement of the acetabular fragment can best be treated by a short period of immobilization in bed

While there is general agreement in the treatment of undisplaced central acetabular fractures there is a diversity of opinion on the treatment of *central acetabular fractures with central dislocation of the femoral head* The surgical treatment of these fractures is difficult (Bohler 1966, Allgower 1966) and there are many who advocate a rather strict conservative line of treatment (Eichenholtz & Stark 1964, Nicoll 1966. Bohler 1966, Tipton et al 1975 Jahna 1976) Others advocate surgical treatment Armstrong (1948) recommended early arthrodesis Westerborn (1954) cup arthroplasty and others osteosynthesis with plate and screws (Judet, Judet & Letournel 1964, Letournel 1966, Palean & Gualtieri 1971) Even primary total hip replacement has been mentioned in the treatment of these fractures (Coventry 1974) Furthermore, some surgeons point out that all central fracture-dislocations should and can best be treated by conservative methods, i e longitudinal and lateral traction and perhaps reduction under general anesthesia, and recommend open reduction and osteosynthesis only in fractures engaging the superior dome where closed treatment has failed in reducing both the femoral head and the acetabular roof accurately (Rowe & Lowell 1961 Gothlin & Hindmarsh 1970, Carnsale et al 1975)

There is however, a general consensus of opinion that the ultimate aim should be as perfect a restoration of the acetabulum femoral head relationship as possible (Gothlin & Hindmarsh 1970 Carnsale et al 1975 Tipton et al 1975) However, this is a task sometimes difficult to carry out and incongruity between the articulating surfaces becomes accepted as this in many cases does not result in impaired function (Rowe & Lowell 1961, Nicoll 1966, Austin 1971, Tipton et al 1975)

This follow up included 36 patients with central acetabular fractures with varying degree of central dislocation of the femoral head Thirty-one patients were treated conservatively and 5 surgically As regards the conservative treatment no strict line of treatment was observed some patients being immobilized in bed only and some being put into traction, which in most cases was applied through the tibial tuberosity The superior dome was intact in 15 of the 31 patients conservatively treated and 13 of them, i e 87 per cent had excellent or good clinical result No significant difference in clinical results could be observed between those 6 patients who had a good reduction of the femoral head and those 9 who had a less satisfactory reduction In 11 of these 15 patients the dislocation of the femoral head was moderate, and in 4 it was severe It is noticeable that those 2 patients who had a severe central dislo-

Judet, Judet & Letournel (1964) have presented a classification based on radiologic examinations including besides AP view also external and internal oblique views in order to determine the anatomy of these fractures as exactly as possible Since the therapeutic approach of these authors is strictly surgical, the aim of their classification and radiologic methods has merely been to study the fracture lines in each case to guide them in open reduction Our approach to the treatment of these fractures has mainly been conservative, and in the present study most cases have not been radiologically examined with oblique projections

We have chosen a classification similar to that of Stewart & Milford (1954), based on the degree of central dislocation of the femoral head and the involvement of the weight bearing area i e whether the superior dome was fractured or not

Different classifications have also been presented for *posterior* acetabular fractures Many authors include in their series of posterior fracture-dislocations, simple posterior dislocations of the femoral head and posterior dislocations of the femoral head in combination with fractures of the femoral head or the acetabular floor Posterior *fracture-dislocations are divided in groups* depending on the size and number of posterior fragment(s), the stability of the joint and if in combination with the posterior dislocation a fracture of the femoral head, or the acetabular floor is present (Thompson & Epstein 1951, Stewart & Milford 1954)

In this material we have not included simple posterior dislocations of the femoral head or posterior dislocations of the femoral head combined with fractures of the femoral neck, but limited the investigation to posterior acetabular fractures with or without posterior dislocation of the femoral head We have therefore chosen the classification which was presented by Waller in 1955

Since the cause of injury the classification the therapeutic approach and the late results differ between central and posterior acetabular fractures we have in this study chosen to describe these two main groups separately

Central acetabular fractures

There is great confusion in the literature about the treatment of central fracture-dislocations There is a better agreement as regards the treatment of central acetabular fractures without central dislocation of the femoral head This investigation has included central acetabular fractures *without central dislocation of the femoral* head as well as central fractures with central intrapelvic protrusion of the femoral head

In order to minimize the examiner's subjective opinion, a point system suggested by d'Aubigné & Postel 1954, later modified by Charnley in 1972 was followed at the assessment of results A summary of the points for pain and walking has been made to facilitate a comparison with other reported results and between clinical results and radiologic appearance

Central fractures without central dislocation of the femoral head usually offer no problems These fractures are generally treated by conservative methods Some recommend bed rest only (Rowe & Lowell 1961 Judet Judet & Letournel 1964 Solheim & Skrede 1973) and others a short period of traction (Wechselberger 1956 Pearson & Hargadon 1962 Eichenholtz & Stark 1964) Excellent or good results in 90 to 100 per cent are reported by Rowe & Lowell and Eichenholtz & Stark

This investigation included 30 patients all treated conservatively Twenty-eight were immobilized in bed only and 2 were put into traction Time for immobilization was 2 weeks Twenty-seven of 30 i e 90 per cent had excellent or good result which is well comparable with other reported results The results for patients with displacement of the acetabular fragment were even better than for those without displacement All patients with fair or poor result had undisplaced fractures Only 3 of 29 patients radiologically examined showed signs of osteoarthrosis and 2 of these had in addition a necrosis of the femoral head

It seems that acetabular fractures without central dislocation of the femoral head with or without displacement of the acetabular fragment can best be treated by a short period of immobilization in bed

While there is general agreement in the treatment of undisplaced central acetabular fractures there is a diversity of opinion on the treatment of *central acetabular fractures with central dislocation of the femoral head* The surgical treatment of these fractures is difficult (Bohler 1966 Allgower 1966) and there are many who advocate a rather strict conservative line of treatment (Eichenholtz & Stark 1964 Nicoll 1966 Bohler 1966 Tipton et al 1975 Jahna 1976) Others advocate surgical treatment Armstrong (1948) recommended early arthrodesis Westerborn (1954) cup arthroplasty and others osteosynthesis with plate and screws (Judet Judet & Letournel 1964 Letournel 1966 Palean & Gualtieri 1971) Even primary total hip replacement has been mentioned in the treatment of these fractures (Coventry 1974) Furthermore some surgeons point out that all central fracture-dislocations should and can best be treated by conservative methods i e longitudinal and lateral traction and perhaps reduction under general anesthesia and recommend open reduction and osteosynthesis only in fractures engaging the superior dome where closed treatment has failed in reducing both the femoral head and the acetabular roof accurately (Rowe & Lowell 1961 Gothlin & Hindmarsh 1970 Carnsale et al 1975)

There is however a general consensus of opinion that the ultimate aim should be as perfect a restoration of the acetabulum femoral head relationship as possible (Gothlin & Hindmarsh 1970 Carnsale et al 1975 Tipton et al 1975) However this is a task sometimes difficult to carry out and incongruity between the articulating surfaces becomes accepted as this in many cases does not result in impaired function (Rowe & Lowell 1961 Nicoll 1966 Austin 1971 Tipton et al 1975)

This follow up included 36 patients with central acetabular fractures with varying degree of central dislocation of the femoral head Thirty-one patients were treated conservatively and 5 surgically As regards the conservative treatment no strict line of treatment was observed some patients being immobilized in bed only and some being put into traction which in most cases was applied through the tibial tuberosity The superior dome was intact in 15 of the 31 patients conservatively treated and 13 of them i e 87 per cent had excellent or good clinical result No significant difference in clinical results could be observed between those 6 patients who had a good reduction of the femoral head and those 9 who had a less satisfactory reduction In 11 of these 15 patients the dislocation of the femoral head was moderate and in 4 it was severe It is noticeable that those 2 patients who had a severe central dislo

cation and a less satisfactory reduction of the femoral head both had excellent results Thirteen of the 15 patients were radiologically examined and 7 of them had osteoarthrosis (54 per cent) (2 of the 6 patients with good reduction of the femoral head and 5 of the 7 patients with less satisfactory reduction of the femoral head) Our results are in accordance with the results of Rowe & Lowell (1961), Gothlin & Hindmarsh (1970) and Nerubay et al (1973) who found 70 to 90 per cent excellent or good results in innerwall fractures treated conservatively It seems that these fractures can be adequately treated with conservative methods, i e longitudinal and lateral traction for 6 8 weeks If traction fails in reducing the femoral head an attempt during general anesthesia should be performed It seems that anatomical reduction of the acetabular fragments is of less importance in these fractures The important thing is to reduce the femoral head under the acetabular roof and keep it there Like Rowe & Lowell Eichenholtz & Stark and Austin we found that traction usually had little effect in reducing the acetabular fragments but yet it seemed that nature had filled in the gap between the femoral head and the acetabular fragments so that a smooth congruent socket had developed

Sixteen patients of the 31 with central fracture-dislocations treated conservatively had the superior dome fractured Late results were not so good in this group, and only 38 per cent had excellent or good clinical results Good reduction of the femoral head (8 patients) gave better results than less satisfactory reduction (8 patients) Worst results were seen in the 9 patients who had a severe central dislocation of the femoral head Fourteen patients were radiologically examined and 9 of them i e 64 per cent had osteoarthrosis (4 of the 8 patients with good reduction and 5 of the 6 patients with less satisfactory reduction) The present results are similar to those of Rowe & Lowell who found 36 per cent excellent or good results in superior dome fractures

Only 5 patients were treated surgically all had central fractures with severe central dislocation of the femoral head with the fracture engaging the superior dome Only one patient achieved a good clinical result In only 2 patients the femoral head was reduced

Analysis of the results in the present series show similarities to other reported results Fractures of the inner wall both with moderate and severe central dislocation of the femoral head gave excellent or good clinical results in the majority of cases with conservative treatment

Central fracture-dislocations with fractures of the acetabular roof in which the femoral head and the superior dome are satisfactorily reduced by traction or manipulation can be adequately treated by conservative methods When however closed treatment has failed in reducing the femoral head and the acetabular roof accurately primary open reduction appears to be a rational approach to the problem It is in line with the modern principles of management of intraarticular fractures especially in weightbearing joints because it is aimed at restoring congruity of the weightbearing articular surfaces However it is a major undertaking the technique is difficult and demands considerable surgical experience and not all patients requiring treatment will be found to be suitable for it Major associated head and chest injuries severe chock severe comminution of the fracture and advanced age may all contraindicate this form of treatment Apart from these limitations on the use of open reduction as a standard method of treatment there are other points that should not be forgotten

It is never possible to make an accurate assessment of the damage of the articular cartilage possibly caused by the injury. Because such damage may be a major contributory factor in determining the development of later osteoarthrosis or femoral head necrosis, simple restoration of the anatomy of the acetabulum may not be adequate. Furtheron Porter (1973) and Batra (1976) have stated that for technical reasons accurate reduction at operation is not always possible and therefore joint congruity may not be achieved in a proportion of patients. Letournel (1966) in his series of 170 operated patients (including 42 posterior fractures) described perfect reduction of the acetabular fragments in 62 per cent and perfect reduction of the femoral head in 85 per cent.

It is difficult to state categorically the indications for open reduction and each case must be considered on its own merits. However, we agree with Carnsale et al. (1975) and Batra (1976) that in relatively young patients who have displaced fractures with involvement of the roof, without undue comminution, this line of treatment may be considered desirable in the hope of reducing displacement and preventing deformity and such premature degeneration in the hip joint as may result solely from uncorrected deformity.

Posterior fractures

While there is confusion about the treatment of central fracture-dislocations, there seems to be greater unity regarding the treatment of posterior fracture-dislocations. The posterior part of the acetabulum has not a weightbearing function but has merely a stabilizing effect on the joint. Most authors agree that a posterior dislocation of the femoral head should be regarded as an emergency and the dislocation should be reduced acute (Stewart & Milford 1954, Waller 1955, Brav 1962, Epstein 1974, Ender 1976). Posterior acetabular fractures without posterior dislocation of the femoral head and without displacement of the acetabular fragment(s) are generally treated by conservative methods, i.e. immobilization in bed or traction for a few weeks (Waller 1955, Nicoll 1966). In posterior fracture-dislocations the important thing is that the dislocated femoral head is reduced to its normal position and is kept there. There is an absolute indication for operation when the femoral head cannot be brought to its normal position by conservative methods, i.e. manipulation during general anesthesia or when there is an involvement of the sciatic nerve (Waller 1955, Rowe & Lowell 1961, Brav 1962, Nicoll 1966, Epstein 1974, Ender 1976). Most authors agree that instability of the joint after reduction of the femoral head requires surgical exploration and osteosynthesis of the acetabular fragment (Rowe & Lowell 1961, Brav 1962, Stewart et al. 1975, Ender 1976). The instability is demonstrated at the time of reducing the dislocation (Nicoll 1966, Ender 1976). If the joint is regarded as stable after reduction of the femoral head, but a posterior fragment remains displaced, some advocate surgical treatment (Waller 1955, Epstein 1974, Ender 1976) and others conservative treatment (Bohler 1954, Brav 1962, Nicoll 1966).

In this material 3 patients had posterior fractures with a small to moderate undisplaced fragment. All were treated conservatively with immobilization in bed for 1-2 weeks and all had excellent clinical results. It appears that these fractures can best be treated by immobilization in bed for 1-2 weeks.

cation and a less satisfactory reduction of the femoral head both had excellent results Thirteen of the 15 patients were radiologically examined and 7 of them had osteoarthrosis (54 per cent) (2 of the 6 patients with good reduction of the femoral head and 5 of the 7 patients with less satisfactory reduction of the femoral head) Our results are in accordance with the results of Rowe & Lowell (1961), Gothlin & Hindmarsh (1970) and Nerubay et al (1973) who found 70 to 90 per cent excellent or good results in innerwall fractures treated conservatively It seems that these fractures can be adequately treated with conservative methods, i e longitudinal and lateral traction for 6 8 weeks If traction fails in reducing the femoral head an attempt during general anesthesia should be performed It seems that anatomical reduction of the acetabular fragments is of less importance in these fractures The important thing is to reduce the femoral head under the acetabular roof and keep it there Like Rowe & Lowell, Eichenholtz & Stark and Austin we found that traction usually had little effect in reducing the acetabular fragments but yet it seemed that nature had filled in the gap between the femoral head and the acetabular fragments, so that a smooth congruent socket had developed

Sixteen patients of the 31 with central fracture dislocations treated conservatively had the superior dome fractured Late results were not so good in this group, and only 38 per cent had excellent or good clinical results Good reduction of the femoral head (8 patients) gave better results than less satisfactory reduction (8 patients) Worst results were seen in the 9 patients who had a severe central dislocation of the femoral head Fourteen patients were radiologically examined and 9 of them, i e 64 per cent had osteoarthrosis (4 of the 8 patients with good reduction and 5 of the 6 patients with less satisfactory reduction) The present results are similar to those of Rowe & Lowell who found 36 per cent excellent or good results in superior dome fractures

Only 5 patients were treated surgically, all had central fractures with severe central dislocation of the femoral head with the fracture engaging the superior dome Only one patient achieved a good clinical result In only 2 patients the femoral head was reduced

Analysis of the results in the present series show similarities to other reported results Fractures of the inner wall both with moderate and severe central dislocation of the femoral head gave excellent or good clinical results in the majority of cases with conservative treatment

Central fracture-dislocations with fractures of the acetabular roof in which the femoral head and the superior dome are satisfactorily reduced by traction or manipulation can be adequately treated by conservative methods When however closed treatment has failed in reducing the femoral head and the acetabular roof accurately primary open reduction appears to be a rational approach to the problem It is in line with the modern principles of management of intraarticular fractures especially in weightbearing joints, because it is aimed at restoring congruity of the weightbearing articular surfaces However it is a major undertaking, the technique is difficult and demands considerable surgical experience and not all patients requiring treatment will be found to be suitable for it Major associated head and chest injuries, severe chock severe comminution of the fracture, and advanced age may all contraindicate this form of treatment Apart from these limitations on the use of open reduction as a standard method of treatment there are other points that should not be forgotten

Epstein (1974) had even less good results for patients treated conservatively namely 14 per cent whereas he had 44 per cent good results for patients treated by closed reduction of the femoral head followed by open reduction and osteosynthesis of the acetabular fragment In his material 50 per cent of the patients treated conservatively had unfavourable features of the kind mentioned above However Nicoll (1966) points out that excellent results should be attainable in all posterior fracture-dislocations and only 1/3 will require operation either to restore stability or to remove obstructing fragments Stewart et al (1975) reported on 57 patients with conservatively treated posterior acetabular fractures (Type II III) and 39 (68 per cent) had excellent or good results In 44 patients the posterior dislocation was reduced within 12 hours and this group of patients included all those who had excellent or good results In the present series 8 patients had poor results and 5 of these had unfavourable features i e redislocation of the femoral head unreduced dislocation or combination with a central fracture

Osteoarthrosis and femoral head necrosis are sequelae which as a rule result in impaired function and it cannot be excluded that the fate of the fracture is decided at the time of injury Most authors agree that the cause of avascular necrosis is a disturbed circulation due to injury to the ligament of the femoral head and to the joint capsule in fracture-dislocations (Waller 1955 Elliott 1956 Stewart et al 1975) When the head of the femur becomes dislocated out of the joint cavity the ligamentum teres always ruptures totally which was proved experimentally by Waller (1955) Even if only some of the vessels in the posterior part of the capsule are divided when the femoral head dislocates the circulation in the tightly stretched out capsule is endangered as surviving vessels tend to become compressed and thrombotic Early reduction of the dislocation is of the greatest importance for these reasons (Waller 1955 Elliott 1956) However necrosis of the femoral head and arthrotic changes sometimes develop after trauma in which the hip has not been dislocated , indeed it may even develop without any known injury Consequently it is possible that avascular necrosis after fracture dislocation of the hip is not always caused by destruction of the circulation through the ligamentum teres and the posterior part of the capsule Stewart & Milford (1954) suggested that the force of the injury may be important in determining whether avascular necrosis develops In this type of injury it is reasonable to believe that both the head of the femur and the acetabulum itself sustain damage Radiologically and clinically the head of the femur does not usually show damage unless a piece of bone has been fractured off the head which occurs rarely (Elliott 1956) However a force resulting in an impact to the femoral head may perhaps cause intracellular molecular changes resulting in necrosis of bone as suggested by Stewart & Milford (1954)

Thirty two patients had posterior fractures classified as Type II or III, 14 were treated conservatively, 18 surgically Our indications for surgery have been

1 Remaining displacement of the acetabular fragment(s) (Reports from the patient records regarding stability or instability have not been obtained) Most of the patients were operated upon within 1 week
2 Redislocation of the femoral head
3 Unsuccessful closed reduction
4 Sciatic nerve involvement

Postoperatively some were put into traction and others were immobilized in bed only Time for immobilization was 4 6 weeks The conservative treatment has included closed reduction of the femoral head under general anesthesia and immobilization in bed with or without traction for 3 5 weeks Of the patients treated conservatively, 79 per cent had excellent or good clinical results and of the patients treated surgically, 67 per cent had excellent or good results (Type II treated conservatively 100 per cent excellent or good, Type II treated surgically 70 per cent excellent or good, Type III treated conservatively 67 per cent excellent or good, Type III treated surgically 63 per cent excellent or good)

In 8 patients the posterior acetabular fragment remained displaced after reduction of the femoral head The clinical results were as good for these patients as for the others treated conservatively Thirty two patients with posterior fracture-dislocations of Type II or III were included in the radiologic follow up study Osteoarthrosis and femoral head necrosis were more frequently seen in the patients who had been operated upon (Tables 30 and 31)

The clinical results in this series are in accordance with other reports The results for patients treated conservatively are similar to those of Brav (1962), Nerubay et al (1973) and Stewart et al (1975) who found 60 to 80 per cent excellent or good long term results after conservative treatment of these fractures The results for patients treated surgically are similar to those of Waller (1955), Rowe & Lowell (1961) Brav (1962) Solheim & Skrede (1973) and Stewart et al (1975) who found 60 to 75 per cent excellent or good long term results after surgical treatment

Most important in posterior fracture-dislocations seems to be the reduction of the femoral head and the stability of the joint If these demands can be fulfilled and there is no sciatic nerve palsy the prognosis for these fractures seems to be independent of whether they are treated conservatively or surgically The bad results obtained both after conservative and surgical treatment often depend on the above demands not having been fulfilled For example 1 The posterior dislocation has been missed and the femoral head has not been reduced until after 24 hours In some cases there has been no reduction at all 2 Repeated unsuccessful attempts with closed reduction have been made 3 Redislocation of the femoral head has occurred due to instability

Waller (1955) had only 21 per cent excellent or good results in his patients with Type II and III fractures who had been treated conservatively

5 If the joint is regarded as stable after closed reduction of the femoral head but a moderate to large fragment is still dislocated and there are signs of sciatic nerve involvement open reduction and osteosynthesis should be performed If, however, there is no sign of nerve injury the prognosis is probably not determined of whether these fractures are operated or not

6 If the femoral head has not been dislocated posteriorly and the fragment remains in its place, conservative treatment with immobilization in bed for a short period is adequate

Chapter 6

CONCLUSION

It is difficult to state cathegorically the line of treatment for these fractures. Age and associated injuries have to be considered when deciding about treatment. However, the following general conclusions can be made based on this study and on the study of the literature.

Central acetabular fractures

1. For a detailed analysis of these fractures the radiologic examination should include besides AP views even oblique views.
2. Central acetabular fractures without central dislocation of the femoral head can be adequately treated by a short period of immobilization in bed.
3. Central acetabular fractures with central dislocation of the femoral head, but without fracture of the superior dome can be treated conservatively with traction through the tibial tuberosity, possibly in combination with lateral traction applied through the proximal femur. If traction fails in reducing the femoral head under the intact acetabular roof an attempt during general anesthesia should be made. The traction is continued for 6-8 weeks
4. In central acetabular fractures with central dislocation of the femoral head and fracture of the superior dome an attempt at conservative treatment with traction should be made General anesthesia may be required for reduction. If conservative treatment fails in reducing the femoral head and the acetabular roof accurately, open reduction and osteosynthesis can be considered especially in young patients without undue communution of the fracture.

Posterior acetabular fractures

1. A posterior dislocation of the femoral head should be treated as an emergency and acute reduction should be performed
2. After reduction the radiologic examination should include AP, lateral and oblique projections.
3. When closed reduction fails in reducing the femoral head open reduction of the femoral head and osteosynthesis of the acetabular fragment should be made
4. If instability can be demonstrated at the time of closed reduction of the femoral head the acetabular fragment should be fixed

5 If the joint is regarded as stable after closed reduction of the femoral head but a moderate to large fragment is still dislocated and there are signs of sciatic nerve involvement open reduction and osteosynthesis should be performed If, however, there is no sign of nerve injury the prognosis is probably not determined of whether these fractures are operated or not

6 If the femoral head has not been dislocated posteriorly and the fragment remains in its place, conservative treatment with immobilization in bed for a short period is adequate

CONCLUSION

It is difficult to state cathegorically the line of treatment for these fractures. Age and associated injuries have to be considered when deciding about treatment. However, the following general conclusions can be made based on this study and on the study of the literature

Central acetabular fractures

1. For a detailed analysis of these fractures the radiologic examination should include besides AP views even oblique views.
2. Central acetabular fractures without central dislocation of the femoral head can be adequately treated by a short period of immobilization in bed.
3. Central acetabular fractures with central dislocation of the femoral head, but without fracture of the superior dome can be treated conservatively with traction through the tibial tuberosity, possibly in combination with lateral traction applied through the proximal femur. PART TWO

AN EXPERIMENTAL STUDY

by

Olle Lansinger and Bertil Romanus

INTRODUCTION

The knowledge of the fracture mechanism of central acetabular fractures is mainly based on clinical observations

Some experimental studies have been made on cadavers, violent forces being directed to the trochanteric region by hammers, falling weights or a pendulum The position of the femoral neck in relation to the acetabulum has not been registered Analysis of this position and its possible importance in the production of varying types of acetabular fractures has thus not been possible

The purpose of this investigation has been to design an experimental model by which central acetabular fractures can be produced on cadaver pelves and to determine the conditions (energy and position of the hip joint) under which various types of central acetabular fractures can be produced (fractures of the posterior column, transverse fractures and fractures of the anterior column)

Fracture mechanism

Theories based on clinical materials

Central acetabular fractures are believed to result from a direct blow to the trochanteric region as occurs e g. when pedestrians become knocked down by a car or in falls from heights

The fracture mechanism has been analysed by Cauchoix & Truchet (1951), Wollmar & Wachtler (1956), Judet et al. (1964) and Judet & Letournel (1974).

Cauchoix & Truchet (1951) suggested that depending on the degree of rotation of the femur with this in extension fractures arise either anteriorly or posteriorly in the acetabulum when a force is directed to the greater trochanter. Excluding the view on the importance of the rotation of the femur Wollmar & Wachtler (1956) pointed to the importance of the force being transmitted via the femoral neck and the importance of the femoral head being well centered in the acetabulum.

Judet et al. (1964) and Judet & Letournel (1974) described the theoretical background for posterior rim fractures, fractures of the posterior and anterior column, and transverse fractures. With a force directed to the trochanteric region of the extended hip transverse and posterior fractures were calculated to arise when the femoral neck was internally rotated 50°; transverse fractures when it was internally rotated 0 – 50°, fractures of the anterior column when it was externally rotated 0 – 25° and fractures of the anterior lip when it was externally rotated 50° With the hip joint flexed 90° and with the force acting along the femur, fractures would arise in the posterior rim, posterior lip or the posterior column, or transverse fractures would arise depending on the degree of abduction and adduction.

Previous experimental studies on acetabular fractures

Central acetabular fractures have been produced by Virveaux (1899), Thévenot (1904), Schroeder (1909), Cottalorda (1922), Romani (1928), Cauchoix & Truchet (1951), Creyssel & Schnepp (1961) and Pearson & Hargadon (1962) (Table 35).

They suggested that different degrees of rotation of the femur resulted in different types of fractures when blows were directed to the trochanteric region.

INTRODUCTION

The knowledge of the fracture mechanism of central acetabular fractures is mainly based on clinical observations.

Some experimental studies have been made on cadavers, violent forces being directed to the trochanteric region by hammers, falling weights or a pendulum. The position of the femoral neck in relation to the acetabulum has not been registered. Analysis of this position and its possible importance in the production of varying types of acetabular fractures has thus not been possible.

The purpose of this investigation has been to design an experimental model by which central acetabular fractures can be produced on cadaver pelves and to determine the conditions (energy and position of the hip joint) under which various types of central acetabular fractures can be produced (fractures of the posterior column, transverse fractures and fractures of the anterior column)

Fracture mechanism

Theories based on clinical materials

Central acetabular fractures are believed to result from a direct blow to the trochanteric region as occurs e.g. when pedestrians become knocked down by a car or in falls from heights

The fracture mechanism has been analysed by Cauchoix & Truchet (1951), Wollmar & Wachtler (1956), Judet et al. (1964) and Judet & Letournel (1974).

Cauchoix & Truchet (1951) suggested that depending on the degree of rotation of the femur with this in extension fractures arise either anteriorly or posteriorly in the acetabulum when a force is directed to the greater trochanter. Excluding the view on the importance of the rotation of the femur Wollmar & Wachtler (1956) pointed to the importance of the force being transmitted via the femoral neck and the importance of the femoral head being well centered in the acetabulum.

Judet et al. (1964) and Judet & Letournel (1974) described the theoretical background for posterior rim fractures, fractures of the posterior and anterior column, and transverse fractures With a force directed to the trochanteric region of the extended hip transverse and posterior fractures were calculated to arise when the femoral neck was internally rotated 50°, transverse fractures when it was internally rotated 0 – 50°, fractures of the anterior column when it was externally rotated 0 – 25° and fractures of the anterior lip when it was externally rotated 50° With the hip joint flexed 90° and with the force acting along the femur, fractures would arise in the posterior rim, posterior lip or the posterior column, or transverse fractures would arise depending on the degree of abduction and adduction.

Previous experimental studies on acetabular fractures

Central acetabular fractures have been produced by Virveaux (1899), Thévenot (1904), Schroeder (1909), Cottalorda (1922), Romani (1928), Cauchoix & Truchet (1951), Creyssel & Schnepp (1961) and Pearson & Hargadon (1962) (Table 35)

Table 35 Earlier experimental works on central acetabular fractures

Author	Reported experiments	Reported acetabular fractures	Fractures of the femoral neck or shaft
Virveaux – 1899	17	4	4
Schroeder 1909	14	4	8

Romani – 1928	22	1	11
Creyssel & Schnepp 1961	12	5	
Pearson & Hargadon 1962	11	11	

Cauchoix & Truchet (1951) stated that it was necessary with a violent force and a solid femoral neck to produce experimental acetabular fractures. They suggested that different degrees of rotation of the femur resulted in different types of fractures when blows were directed to the trochanteric region.

A blow has been directed to the trochanteric region of whole cadavers with a hammer or a wooden club (Virveaux 1899, Schroeder 1909, Cottalorda 1922, Romani 1928), with a falling weight (Creyssel & Schnepp 1961), or with a pendulum (Pearson & Hargadon 1962). Attempts have not been made to produce these fractures by blows in the direction of the femoral neck axis. The exact point for the hit has not been registered and the position of the hip joint at the moment of the blow and the importance of this position for the production of various fracture types have not been analysed.

Posterior acetabular fractures have been produced on cadavers by Waller (1955). In 160 experiments he produced 108 posterior "dashboard" fractures by a falling weight (60 kg from 2 meters) against the knee with the hip and the knee in flexion. He described the conditions under which these fractures could be produced.

– / Information missing

Material

Twenty four cadaver pelves were used (Table 36) They consisted of the pelvic ring with the fifth lumbar vertebra and the proximal 15 – 20 centimeters of both femora The specimens were roughly cleaned from soft tissues except for the ligaments which were left intact The cadaver pelves were all from individuals who had died from non skeletal diseases mainly cardiovascular There was osteoarthrosis in two hips one of which had been operated with an osteotomy The remaining pelves were all radiographically normal The known age distribution of the individuals was 27 – 85 years It was not possible in all to establish the exact duration of premortal bed-rest or the height and weight from the medical records

The specimens were either used on the day of preparation or stored in a deep freeze (–20° C) and thawed at room temperature 12 – 24 hours prior to the experiment

Method

The specimens were divided into two parts in a sagittal plane through the middle of the vertebra L 5 the sacrum and the coccyx. Anteriorly the division was carried through the sym physis The resected surfaces were fixed in a metal box (31 x 18 x 4 centimeters) with epoxy resin (Plastic Padding®) The metal box was screwed onto a stand which was adjustable (Figs 33 and 34)

One object of these experiments has been to transmit the force of the pendulum along the femoral neck axis Another has been to define the degrees of rotation, abduction and adduc tion of the femur for each individual test To achieve this adjustments of the position of the specimen had to be done and the exactness was determined by radiologic examination of the specimen set-up in 2 perpendicular planes prior to each experiment

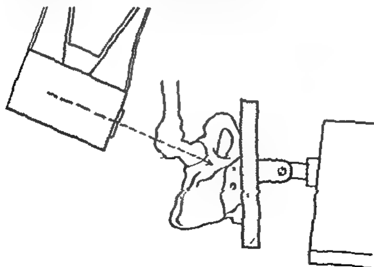

Fig 33 Experimental set-up in experiments with the femur in extension (left hip)

Energy

The greater trochanter was subjected to a blow by a pendulum with its centre in the ceiling and with a radius of 225 centimeters and a weight of 35 kilos. The fall varied from 45 – 140 centimeters corresponding to an energy of 155 – 480 Nm.

A total of 44 experiments was performed, the first 32 with the femur in extension and the last 12 with the femur in 60 – 90° flexion. With extension we mean that the femoral shaft is paralell to a plane through the anterior superior iliac spine and the pubic crest (Boyd et al. 1958).

Definitions

Measurements of the position of the femur, the striking point of the pendulum and the direction of its force were done on radiographs; 3 perpendicular planes were used; sagittal, frontal, and transverse. The metal box acted as a sagittal plane.

The femoral neck axis The centre of the femoral head has been determined by concentric circles. A line has been drawn from the centre of the femoral head to the midpoint of the border between the femoral head and neck. This line has been called the femoral neck axis (Figs. 35 and 36).

The longitudinal axis of the femur· This has been determined on radiographs by drawing a line through the centre of the femoral shaft.

Radiologic determination of the position of femur

The angle of anteversion of the femoral neck is estimated at between 12 – 14° (Rydell 1966). The individual variation is great (–13 to 55°) (Backman 1957) To determine the angle of anteversion it is necessary to have the complete femur. For this study, however, the degree of rotation of the femoral neck has been determined by the degree the femoral neck axis

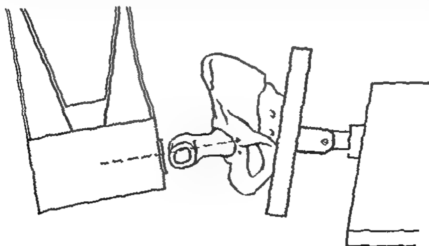

Fig 34. Experimental set up in experiments with the femur in flexion (right hip)

formed in relation to the frontal plane (in experiments with the femur in extension) and to the transverse plane (with the femur in 90° flexion)

The position of the femur has been defined in the following projections

Experiments with the femur in extension

In the *vertical view* of the specimen (Fig 35) the angle between the axis of the femoral neck and a frontal plane was determined

+ indicates that the femoral neck axis forms an angle posterior to the frontal plane "external rotation" (Fig 35 A)

− indicates that the femoral neck axis forms an angle anterior to the frontal plane "internal rotation" (Fig 35 B)

In the *AP (anteroposterior) view* of the specimen the degree of abduction and adduction in relation to the sagittal plane was determined (Fig 33)

Experiments with the femur in flexion

In the *AP view* of the specimen (Fig 34) the angle between the femoral neck axis and a transverse plane was determined (Fig 36)

+ indicates that the femoral neck axis forms an angle inferior to the transverse plane "ex

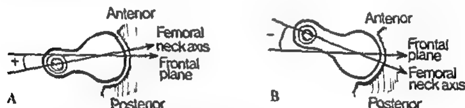

Fig 35 Vertical view of the right hip with the femur in extension (perpendicular to the paper plane) A + indicates that the femoral neck axis forms an angle posterior to the frontal plane ("external rotation") B − indicates that the femoral neck axis forms an angle anterior to the frontal plane ("internal rotation")

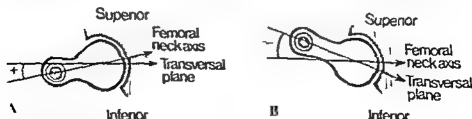

Fig 36 AP view of right hip with the femur in 90° flexion (perpendicular to the paper plane) A + indicates that the femoral neck axis forms an angle inferior to the transverse plane ("external rotation") B − indicates that the femoral neck axis forms an angle superior to the transverse plane ("internal rotation")

ternal rotation" (Fig. 36 A).

—: indicates that the femoral neck axis forms an angle superior to the transverse plane, "internal rotation" (Fig 36 B).

In the *vertical view* of the specimen the degree of abduction and adduction in relation to the sagittal plane was determined.

Position of the femur (Tables 37, 38 and 40)

In 32 experiments the femur was positioned in extension, the degree of combined external or internal rotation was varied. In 12 experiments the femur was positioned in flexion, the degree of combined abduction or adduction was varied. In 7 of these experiments the degree of flexion was 85 – 90° and in 5 60 – 75°

Preliminary study

Based on the reports of previous experimental work and on the theories of the fracture mechanism in central acetabular fractures a preliminary study of 12 experiments was carried out (experiments 1 – 12) (Table 37).

Set-up of specimen The pelvic specimen was placed on the stand upside down with the hip joint extended (Fig. 33). In the first 8 experiments the pendulum hit the greater trochanter at the lowest point of the pendulum course In the following 4 experiments the blow was directed to the trochanter before the lowest point of the pendulum course as it in this way was easier to obtain the force along the femoral neck axis The energy, the direction of force and the position of the hip joint varied (Table 37).

Results of the preliminary study (Table 37)

In experiments 1, 3, 6, and 7 the blow hit the trochanter with the force directed inferior to the femoral neck axis resulting in a valgus effect This resulted in pertrochanteric fractures in experiments 1, 6 and 7 In experiments 6 and 7 transverse acetabular fractures were also achieved and in experiment 3, a posterior column fracture was obtained In experiment 4 the blow hit the trochanter with the force posterior to the femoral neck axis and a femoral neck fracture and an anterior column fracture were produced In experiments 5, 8, and 9 the force was transmitted ideally as checked in the AP and vertical projections in experiment 5 a T fracture was produced, in experiment 8 a transverse fracture and in experiment 9 a posterior column fracture In specimen 6 (experiment 8) an intertrochanteric osteotomy according to Wainwright had been carried out In this case there was a coxa vara which facilitated the blow in the direction of the femoral neck axis In this experiment an axial compression fracture of the femoral neck was also produced

In experiment 9 an attempt was made to stabilize the hip joint by a Kirschner wire passed along the femoral neck axis into the acetabulum After the pendulum hit it was noted that an abduction of 35° had occurred as indicated by bending of the wire In experiments 10, 11, and 12 we tried to stabilize the hip joint by not thawing the specimens completely The force was in these experiments transmitted ideally along the femoral neck axis A pertrochanteric

Table 37 Experimental acetabular fractures – hip in extension Preliminary study

Experiment	Energy (Nm)	Position of femur: Abduction (Abd) or adduction (Add) degrees	Position of femur: Rotation degrees	Result: Acetabular fracture	Result: Femoral neck or pertrochanteric fracture	Remarks
1	155	–	–	–	Pertrochanteric	
2	258	–	–	Vertical fracture line anteriorly		
3	430		–	Posterior column	–	
4	430	Abd 4	+10	Anterior column	Femoral neck	
5	430	Add 4	+17	T fracture		
6	430	Abd 5	10	Transverse	Pertrochanteric	
7	430	Add 10	10	Transverse	Pertrochanteric	
8	430	Add 6	+15	Transverse	Femoral neck	osteoarthrosis
9	430	Add 10	+8	Posterior column		
10	310	Add 18	+16	–		not fully thawed
11	310	Add 10	+9		Pertrochanteric	not fully thawed
12	310	Add 20	+4	Vertical fracture line posteriorly	–	not fully thawed

compression fracture was produced in one experiment (11) and a vertical fracture line posteriorly in the acetabulum in another (12) There were no other fractures in the acetabulum or pelvis probably owing to a change of the physical properties (e.g stiffness of the soft tissues)

Nine fractures were produced in 12 experiments in this preliminary study Three were transverse fractures with only a fracture line through the middle of the acetabulum One was a T-fracture through the anterior and posterior columns Two were anterior fractures one of which was a fracture of the anterior column and the other only a vertical fracture line anteriorly Three were fractures posteriorly in 2 of which the posterior column was fractured In one there was only a fracture line posteriorly The femoral head was not dislocated centrally in any experiment

Conclusion of the preliminary study

This preliminary study gave the conditions necessary for the best position of the specimen to produce an acetabular fracture with the pendulum hitting the trochanter with the hip joint in extension It was found necessary to strike the femoral neck in an axial direction to avoid pertrochanteric and femoral neck fractures The femur had in these 12 preliminary experiments been fixed with silk sutures in the soft tissues in experiments 1 – 8 been transfixed by a Kirschner wire in experiment 9 and been half thawed in experiments 10 – 12 To obtain a better centering of the femoral head and also a stabilization of the femur in the further experiments strings were threaded through canals drilled in the femur and the iliac wing and through the obturator foramen in directions corresponding to normal muscles

ternal rotation" (Fig. 36 A).

–, indicates that the femoral neck axis forms an angle superior to the transverse plane, "internal rotation" (Fig. 36 B).

In the *vertical view* of the specimen the degree of abduction and adduction in relation to *the sagittal plane* was determined

Position of the femur (Tables 37, 38 and 40)

In 32 experiments the femur was positioned in extension, the degree of combined external or internal rotation was varied. In 12 experiments the femur was positioned in flexion, the degree of combined abduction or adduction was varied *In 7 of these experiments the degree* of flexion was 85 – 90° and in 5 60 – 75°

Preliminary study

Based on the reports of previous experimental work and on the theories of the fracture mechanism in central acetabular fractures a preliminary study of 12 experiments was carried out (experiments 1 – 12) (Table 37).

Set-up of specimen The pelvic specimen was placed on the stand upside down with the hip joint extended (Fig 33). In the first 8 experiments the pendulum hit the greater trochanter at the lowest point of the pendulum course. In the following 4 experiments the blow was directed to the trochanter before the lowest point of the pendulum course as it in this way was easier to obtain the force along the femoral neck axis. The energy, the direction of force and the position of the hip joint varied (Table 37).

Results of the preliminary study (Table 37)

In experiments 1, 3, 6, and 7 the blow hit the trochanter with the force directed inferior to the femoral neck axis resulting in a valgus effect This resulted in pertrochanteric fractures in experiments 1, 6 and 7 In experiments 6 and 7 transverse acetabular fractures were also achieved and in experiment 3, a posterior column fracture was obtained In experiment 4 the blow hit the trochanter with the force posterior to the femoral neck axis and a femoral neck *fracture and an anterior column fracture were produced In experiments* 5, 8, and 9 the force was transmitted ideally as checked in the AP and vertical projections in experiment 5 a T-fracture was produced, in experiment 8 a transverse fracture and in experiment 9 a posterior column fracture In specimen 6 (experiment 8) an intertrochanteric osteotomy according to Wainwright had been carried out In this case there was a coxa vara which facilitated the blow in the direction of the femoral neck axis In this experiment an axial compression fracture of the femoral neck was also produced

In experiment 9 an attempt was made to stabilize the hip joint by a Kirschner wire passed along the femoral neck axis into the acetabulum After the pendulum hit it was noted that an abduction of 35° had occurred as indicated by bending of the wire In experiments 10, 11, and 12 we tried to stabilize the hip joint by not thawing the specimens completely. The force was in these experiments transmitted ideally along the femoral neck axis A pertrochanteric

Table 37 Experimental acetabular fractures – hip in extension Preliminary study

Ex periment	Energy (Nm)	Position of femur: Abduction (Abd) or adduction (Add) degrees	Rotation degrees	Result: Acetabular fracture	Femoral neck or pertrochanteric fracture	Remarks
1	155	–	–	–	Pertrochanteric	
2	258	–	–	Vertical fracture line anteriorly	–	
3	430	–	–	Posterior column	–	
4	430	Abd 4	+10	Anterior column	Femoral neck	
5	430	Add 4	+17	T–fracture		
6	430	Abd 5	–10	Transverse	Pertrochanteric	
7	430	Add 10	10	Transverse	Pertrochanteric	
8	430	Add 6	+15	Transverse	Femoral neck	osteoarthrosis
9	430	Add 10	+8	Posterior column		
10	310	Add 18	+16	–	–	not fully thawed
11	310	Add 10	+9		Pertrochanteric	not fully thawed
12	310	Add 20	+4	Vertical fracture line posteriorly		not fully thawed

compression fracture was produced in one experiment (11) and a vertical fracture-line posteriorly in the acetabulum in another (12) There were no other fractures in the acetabulum or pelvis probably owing to a change of the physical properties (e g stiffness of the soft tissues)

Nine fractures were produced in 12 experiments in this preliminary study Three were transverse fractures with only a fracture-line through the middle of the acetabulum One was a T-fracture through the anterior and posterior columns Two were anterior fractures one of which was a fracture of the anterior column and the other only a vertical fracture line anteriorly Three were fractures posteriorly in 2 of which the posterior column was fractured In one there was only a fracture line posteriorly The femoral head was not dislocated centrally in any experiment

Conclusion of the preliminary study

This preliminary study gave the conditions necessary for the best position of the specimen to produce an acetabular fracture with the pendulum hitting the trochanter with the hip joint in extension It was found necessary to strike the femoral neck in an axial direction to avoid pertrochanteric and femoral neck fractures The femur had in these 12 preliminary experiments been fixed with silk sutures in the soft tissues in experiments 1 – 8 been transfixed by a Kirschner wire in experiment 9 and been half thawed in experiments 10 12 To obtain a better centering of the femoral head and also a stabilization of the femur in the further experiments strings were threaded through canals drilled in the femur and the iliac wing and through the obturator foramen in directions corresponding to normal muscles

ternal rotation" (Fig 36 A)

Experimental series

Experiments with the femur in extension

Special set-up was done according to the conclusions in the preliminary study. The pelvis was upside down and the femur extended. The femoral shaft was stabilized to the pelvis The pendulum hit the trochanter before the lowest point of its course.

Results (Table 38)

The first 4 experiments (13 – 16) in this series were carried out with lower energy than previously, as in the preliminary study the best position of the specimen had been determined and it was thought that maximum force would be concentrated to the acetabulum without much being lost in the femoral neck or other tissues. In one experiment (13) a transverse fracture was produced through both columns In the other 3 no fracture was obtained

The energy was then increased to 480 Nm in experiments 17 – 29 In all of these the blow was ideal (with the force along the femoral neck) with the degree of rotation varying from maximal external to maximal internal In 10 experiments transverse fractures were obtained in one an anterior column fracture and in one a vertical fracture-line posteriorly In one experiment (29) no fracture was produced despite ideal position A possible explanation is that the pelvis was from a strong individual (Table 36) and the energy used was not enough to create a fracture A summary of experiments 17 – 29 is given in Table 39 in which it is demonstrated that the degree of rotation has not influenced the localization of the fracture The degree of adduction in these experiments varied between [illegible] – 18°

Ten transverse fractures were produced in experiments 17 29 In [illegible] of these both columns were fractured with a displacement between the acetabular fragments of 1 1.5 centimeters In 2 experiments there was only a horizontal fracture line through the acetabulum In one experiment there was an anterior column fracture and in one a vertical fracture line posteriorly

In experiments 1 – 29 a central dislocation of the femoral head occurred only once This was interpreted as a result of both the symphysis and the sacrum being stably fixed in the epoxy resin without possibility of individual movement In experiments 30 – 44 these structures were fixed separately offering the possibility to move in the sagittal plane In 3 experiments (30 – 32) with unchanged energy and blow on the extended hip joint the degree of rotation was varied from maximal internal (–6°) to external rotation (+18°) Two anterior column fractures were produced without dislocation of the femoral head (30 and 32) and one extra-articular fracture through the ramus superior ossis pubis (31)

Comment In the experiments with the femur in extension this was maximal internally rotated in 7 The measured angles between the femoral neck axis and the frontal plane varied between –4 to –16° Three transverse fractures and 2 fractures of the anterior column were produced In 2 experiments the femur was maximal externally rotated and this resulted in a fracture through the anterior column in one experiment

A study was made to obtain an idea of the rotation in the hip joint with the femur in extension Both hips in 3 complete pelvic specimens were radiologically examined with the femur in maximal external and internal rotation respectively The combined external and internal rotation in the 6 hips varied between 20 40° Maximal internal rotation varied from +15 to 15° and maximal external rotation from +20 to 44°

Experiments with the femur in flexion

On the extended hip joint no difficulties had been encountered in producing transverse or anterior fractures irrespective of the degree of rotation To try to produce posterior column fractures experiments were carried out on flexed hip joint In these the degree of abduction and adduction was varied. By adduction of the femur we wanted to concentrate the energy to the posterior column.

Results (Table 40)

After 2 preliminary experiments (33 and 34) ideal experimental conditions were obtained. With the hip joint flexed 60 – 90° a blow could be directed with almost optimal force concentration along the femoral neck axis.

Ten experiments (35 – 44) were carried out. In 4 of these with the femur in 23 – 40° adduction no acetabular fracture was produced. In one experiment with the femur in neutral position a transverse fracture was produced. In 5 experiments with abduction 10 – 30° a transverse fracture was produced in 3 and a T fracture in one (Table 41).

Of 5 fractures produced in this series 4 were transverse and one a T fracture. The transverse fractures were all fractures through both the posterior and anterior columns. In 2, the femoral head was dislocated centrally 3 – 4 centimeters and in one of them the superior dome was fractured. In 2, the femoral head was not dislocated and in one of them the superior dome was fractured. In one experiment a T-fracture through both columns was produced. The femoral head was not dislocated and the superior dome was intact.

During this experimental investigation it was noticed that it was difficult to detect fractures with no displacement between the acetabular fragments at the radiologic examination When the joint was opened at the dissection the fractures were obvious It was also noticed that oblique projections were necessary to determine the fracture-lines

CONCLUSIONS

The following conclusions of the experiments can be made

1 It is possible to produce central acetabular fractures by an impact to the trochanteric region
2 It is important to hit the trochanter so that the force is transmitted axially through the femoral neck and to stabilize the femoral shaft in order to concentrate the energy and to avoid pertrochanteric or femoral neck fractures
3 The degree of rotation of the femur with this in extension does not seem to influence on the type of acetabular fracture produced
4. An energy of 430 Nm was sufficient to produce acetabular fractures.

DISCUSSION

Various types of acetabular fractures (anterior column, transverse and posterior column) are calculated to arise when the trochanteric region is hit by a force with the femur in extension and varying degree of rotation, or when the force is applied along the axis of the femur with the hip joint in flexion and varying degree of abduction or adduction (Cauchoix & Truchet 1951, Judet et al. 1964, Judet & Letournel 1974) With this concept of the fracture mechanism as a background we have tried to produce experimental acetabular fractures of various types. One problem has been to find an optimal experimental set up. The difficulties to produce other unusual fractures experimentally have learned us the necessity to concentrate the energy to the actual bone and to avoid non axial energy transmission in the bones that are supposed to act as impact bodies (Peterson et al. 1976). To determine the pendulum hit point and the degree of rotation and abduction or adduction of the femur in the experiments it was necessary to x ray the specimen set up before each experiment. Adjustments could then be made.

After a preliminary study the optimal experimental set-up could be defined. The difficulties to achieve this even under controlled laboratory conditions may explain the rareness of the acetabular fracture clinically as compared to the frequent occurrence of pertrochanteric and femoral neck fractures and fractures through the pelvic rami as the result of a trauma to the trochanteric region.

In the first 29 experiments only one central dislocation of the femoral head was achieved This was interpreted as a possible result of both the symphysis and the sacrum being stably fixed in the same epoxy resin. In the following experiments these structures were fixed separately, offered the possibility to move in the sagittal plane. In 7 acetabular fractures 2 resulted in a severe central dislocation of the femoral head.

Only a few isolated posterior column fractures could be produced although the force was transmitted through the femoral neck in maximal internal rotation in several experiments. It was noticed that the possible maximal internal rotation that could be performed in the specimen hip joints was far from that calculated necessary for producing these fractures.

Different amount of energy was used to find the lowest necessary to produce these fractures. The preliminary study showed that all 7 experiments with 430 Nm resulted in acetabular fractures. Out of 9 (in all series) with lower energy only 3 resulted in acetabular fractures Fourteen of 16 experiments with 480 Nm resulted in acetabular fractures on an extended hip joint. In the experiments with the hip joint in flexion the same energy was used in all This seemed to be sufficient to produce transverse fractures with the femur in abduction or neutral position but insufficient in the 4 experiments with the femur in adduction. The posterior column seemed to withstand this energy It is possible that the posterior column fractures are a result of a blow to the knee with the femur in abduction and flexion It is also possible that the energy used in this series was too low. Waller (1955) used an energy of 1200 Nm in producing posterior acetabular fractures on flexed hip Creyssel & Schnepp (1961) used 500 Nm on producing central acetabular fractures on whole cadavers

During this experimental investigation it was noticed that it was difficult to detect fractures *with no displacement* between the acetabular fragments at the radiologic examination. When the joint was opened at the dissection the fractures were obvious. It was also noticed that oblique projections were necessary to determine the fracture-lines.

CONCLUSIONS

The following conclusions of the experiments can be made:

1. It is possible to produce central acetabular fractures by an impact to the trochanteric region.
2. It is important to hit the trochanter so that the force is transmitted axially through the femoral neck and to stabilize the femoral shaft in order to concentrate the energy and to avoid pertrochanteric or femoral neck fractures.
3. The degree of rotation of the femur with this in extension does not seem to influence on the type of acetabular fracture produced
4. An energy of 430 Nm was sufficient to produce acetabular fractures.

SUMMARY

Part one

There are discrepancies in reported series regarding treatment and late results of fractures of the acetabulum The purpose of this investigation has been to perform a study of these fractures with reference to frequency, classification, radiologic appearance, cause of injury, associated injuries, treatment and late results

I During 1963 1973, 123 patients with 124 acetabular fractures were admitted to the Departments of Orthopaedic Surgery at Sahlgren Hospital in Goteborg The study has included central acetabular fractures with and without central dislocation of the femoral head and posterior acetabular fractures with or without posterior dislocation of the femoral head Of the 124 acetabular fractures, 85 were central and 39 posterior

Central acetabular fractures were classified depending on the degree of central dislocation of the femoral head and the involvement of the weightbearing area, i e whether the superior dome was fractured or not

Posterior acetabular fractures were classified depending on the degree of displacement and comminution of the posterior acetabular rim (Waller 1955)

Of 85 patients with *central acetabular fractures* 80 were treated conservatively with immobilization in bed only or with traction through the tibial tuberosity, in some cases in combination with lateral traction through the proximal femur Five patients were treated surgically

Of 39 patients with *posterior acetabular fractures* 19 were treated conservatively with immobilization in bed only or with traction through the tibial tuberosity Twenty patients were treated surgically with open reduction of the acetabular fragment and osteosynthesis

II Onehundred patients with 101 fractures were followed up clinically after 1 1/2 12 years with a mean time for follow up of 6 1 years

Central fractures

The follow up comprised 66 patients with central acetabular fractures, 61 of these were treated conservatively, 5 surgically

Conservative treatment Results were excellent or good in 75 per cent of the 61 patients conservatively treated Thirty patients without central dislocation of the femoral head had excellent or good results in 90 per cent

Fifteen patients with central dislocation of the femoral head without fracture of the superior dome had excellent or good results in 87 per cent

Sixteen patients with central dislocation of the femoral head with fracture of the superior dome had excellent or good results in 38 per cent

Surgical treatment Five patients were treated surgically and one patient had good result and 4 fair

Posterior fractures

Thirty five patients with posterior acetabular fractures were followed up, 17 were treated conservatively and 18 surgically

Conservative treatment The fracture was classified as Type I in 3 patients, as Type II in 5 patients and as Type III in 9 patients The results were excellent or good in 82 per cent (Type I 100 per cent, Type II 100 per cent, Type III 67 per cent)

Surgical treatment The fracture was classified as Type II in 10 patients and as Type III in 8 patients The results were excellent or good in 67 per cent (Type II 70 per cent, Type III 63 per cent)

Sciatic nerve injury

Weakness of the foot extensors was registered in 8 patients Seven of these had a posterior acetabular fracture in combination with a posterior dislocation of the femoral head One patient had a central acetabular fracture without central dislocation of the femoral head At follow up the paresis remained in 5 patients

III Ninety-three patients with 94 acetabular fractures were followed up radiologically (61 patients with central acetabular fractures and 33 with posterior acetabular fractures)

Osteoarthrosis was found in 23 of 61 patients with central acetabular fractures (38 per cent) and in 14 of 33 patients with posterior acetabular fractures (42 per cent)

Avascular necrosis of the femoral head was found in 8 patients 5 with central acetabular fractures and 3 with posterior acetabular fractures

Ectopic ossification was noticed in 13 of 99 patients (13 per cent) who were examined radiologically for more than 1 year

Part two

Based on the reports of previous experimental work and on the theories of fracture mechanism in central acetabular fractures an experimental study of these fractures has been performed. The purpose was to design an experimental model by which central acetabular fractures could be produced on cadaver pelves and to determine the conditions (position of hip joint, and energy) under which various types of central acetabular fractures could be produced.

A preliminary study comprising 12 experiments was performed which gave the optimal specimen set-up

Two experimental series, one with the femur in extension (20 experiments) and one with the femur in flexion (12 experiments) were then performed In these two series 20 acetabular fractures were produced.

We found it important to hit the trochanter so the force was transmitted directly through the femoral neck and to stabilize the femur in order to avoid pertrochanteric or femoral neck fractures. The degree of rotation of the femur with this in extension did not seem to influence on the type of fracture produced When a force was applied to the trochanteric region with the femur in flexion and abduction an energy of 480 Nm was sufficient to produce transverse fractures.

With the same energy applied to the trochanteric region, with the femur in flexion and abduction we did not obtain acetabular fractures, probably owing to insufficient energy.

In a total of 44 experiments 29 acetabular fractures of various types could be produced

ACKNOWLEDGEMENTS

I am most grateful to my chief Professor Bertil Stener for his interest and logic criticism throughout this work

I wish to express my deepest gratitude to Associate Professor Ian Goldie for suggesting the subject of this work for his outstanding way of supervision and enthusiasm which made this work possible for his personal interest in my training in orthopaedic surgery and for translating this work into the English language

I am very much obliged to Margareta Apelskog for her patience and outstanding secretary work

I also want to thank Birgitta Runze at the Biomechanical laboratory Department of Orthopedic Surgery II for her laboratory assistance and Ann Bengtsson and Lucy Persson at the Department of Diagnostic Radiology II for all their patience and technical help with the radiographs

The illustrations were made by Klas Ljung and the photographic work by Carl Sandell and Ole Roos

The final manuscript was typed by Barbro and Roland Johansson

Financial support was provided by

Ulla och Gustaf af Ugglas fond
Åttioårsfonden – Trygg Hansa
Medicinska fakulteten Goteborgs universitet
Goteborgs lakaresallskap

The halo-pelvic apparatus

A clinical, bio-engineering and anatomical study

by
John Patrick O Brien, F R.C S (Edin)

MUNKSGAARD
Copenhagen 1975

To my father and mother,
John and Mollie O'Brien,
Sydney, Australia

LIST OF CONTENTS

Dr Gosta Elfstrom guided me ably in the new field of electrical engineering and we worked on a project on "Halo-pelvic traction" together with Professor Alf Nachemson who generously sponsored my sabbatical leave in Goteborg and also helped and encouraged the presentation of this thesis

The growth and development of the halo-pelvic apparatus in Hong Kong has been the result of the team work of many people who have given much of their time and energies over the years My sincere thanks to them all

The clinical and experimental studies were financially supported by grants from

University of Hong Kong,
University of Goteborg, Sweden,
The Swedish Board for Technical Development, No 73-3766,
Greta och Einar Askers Stiftelse, Goteborg, Sweden,
Kronprinsessan Lovisas Forening for barnasjukvård, Stockholm, Sweden,
AB Stille-Werner, Stockholm, Sweden,
Down Bros and Mayer & Phelps Ltd , London, England,
Ethicon Foundation The Royal College of Surgeons, Edinburgh, Scotland

ACKNOWLEDGEMENTS

Over the years I have had the great privilege of working with skilled and experienced surgeons who have guided my footsteps in the science of orthopaedics

I would particularly like to mention Professor A R Hodgson, whose guidance, enthusiasm and vision have revealed a whole new dimension in the management of severe spinal disorders. His ideas and ideals are embodied in The Duchess of Kent Children's Orthopaedic Hospital and Convalescent Home, Hong Kong

None of this work would have been possible without the loyal cooperation and expert nursing care of the Matron, Sister Barbara, and the staff there

My apprenticeship in spinal surgery was patiently directed by Professor Arthur Yau, whose particular skill with severe neglected kyphosis has made possible excellent results

Dr Louis Hsu has been a loyal support for seven years and together we have shared the satisfactions and the trials of our work Sister Gabriel, Sister Aquinas and Dr Donald Yue have provided the medical care these patients needed with good humoured understanding of our surgical bias

In the engineering work, Dr J Clark and Mr L Kesterton of the Department of Mechanical Engineering, Hong Kong University, have spent many hours on the problems of design of the apparatus and in the development of the force measuring system

On my sabbatical leave in the Departments of Orthopaedic Surgery I and Medical Electronics in Goteborg, Sweden, I greatly appreciated the help and insight I was given into the fields of medical electronics and biomechanics In particular I would like to thank Professor Henry Wallman of the Laboratory of Medical Electronics and Dr Lars Sonnerup of the Department of Mechanical Engineering, Chalmers University of Technology Dr Kerstin Bostrom was most helpful in the autopsy studies connected with Part IV of the thesis

PART I

THE HALO PELVIC APPARATUS

PREFACE

The rapid development of the halo-pelvic technique was made possible in Hong Kong by the large number of children with gross spinal disorders for whom some successful method of treatment had to be found

Our experiences with these children over the last five years form the principal part of this study In order to be comprehensive, a basic introduction to the apparatus and to the safest procedure for application is outlined in Part I

In Part II, the clinical material, methods of treatment and results are the evidence of our work, and a measure of its success The complications encountered are described in Chapter II of this section For the sake of example and clarity they are dealt with in some detail

Part III describes a combined project, when intravital wireless telemetry was used to measure the forces being transmitted through the spine, and provided confirmation of several of the virtues of the apparatus which beforehand we had only been able to assume

The anatomical studies in Part IV establish the fundamental safety of the preferred landmarks for applying the halo and the hoop to the patient along with some basic studies of the growth and mechanical strength of the bony ilium

As this paper specifically studies the halo-pelvic apparatus, details such as surgical approaches to the spine, respiratory function studies and complications related to surgery have been mentioned only briefly so as not to blur the relevancy of the text

THE HISTORY OF THE DEVELOPMENT OF HALO-PELVIC TRACTION

The concept of halo-pelvic traction is attributed to Dr William Green of Boston, U S A (24), thus it is a little surprising that its clinical development has been so recent In the fifties the skull halo had been developed and perfected by Perry and Nickel (50) who then proceeded to develop a form of pelvic fixation

In 1958 in Hong Kong, Hodgson and Yau used a form of halo-pelvic traction for a patient with tuberculous kyphosis Six threaded pins were inserted into the anterior and posterior superior spines of the ilium and the region of the tubercle of each crest, thus employing the skull halo principle

The first attempts at pelvic fixation by Perry and coworkers, at Rancho Los Amigos, California, involved the use of the skull halo technique directly on the pelvis (51) This produced too much skin tenting around the pins, resulting in skin necrosis and the need for early removal of the apparatus Secondly, they tried using coarsely threaded pins angled directly down the long axis of each of the four superior spines, but, in this instance, the cancellous bone held less than three weeks Part of the problem was that severely paralysed patients had very thin iliac crests which were unable to hold the pins

Garrett (51) used the "button wire technique", placing the buttons on the inside of the pelvis and bringing the wires out on to the pelvic hoop This worked very well for approximately ten weeks, until irritation began and the fixation had to be removed Nelson (42), whilst working at Rancho Los Amigos, developed a three pin unit which could be attached directly to the iliac crests The patients tolerated this quite well, although its fixation to the pelvis required considerable surgery, and there was some drainage in each case

Several other workers had been involved at this stage in the development of pelvic hoop fixation, including Levine (31) The difficulty, throughout, was the problem of obtaining firm fixation on the pelvis It was Dewald and Ray who solved this by using

THE HISTORY OF THE DEVELOPMENT OF HALO-PELVIC TRACTION

Several other workers had been involved at this stage in the development of pelvic hoop fixation, including Levine (31) The difficulty, throughout, was the problem of obtaining firm fixation on the pelvis It was DeWald and Ray who solved this by using

threaded pelvic pins which transfixed the iliac crests They described their experience with their first four patients in 1970 (10)

Our clincal experience began in January 1969, the apparatus and the method of fitting it to the patient have been modified and altered in various ways, for reasons of safety, but the basic technique has remained the same

THE APPARATUS

The halo-pelvic apparatus consists of five basic parts (Figs 2, 3 and 4)

a) The skull halo
b) The pelvic hoop and pins, and their attachments
c) Four extension bars connecting the hoop to the halo
d) The force measuring system, a spring at the base of each of the four extension bars
e) The back winder (Fig 4)

a) Originally, a Rancho type halo was used, the design was simplified to facilitate manufacture and to reduce the weight of the halo This meant elimination of the posterior upward flare (as fusion proximally to the skull has not been necessary in our patients), and of the bushings for locking the halo pins in place Instead, the pins were locked in position by a nut on the threaded pin, external to the skull halo Multiple threaded holes were added around the perimeter, allowing a wide selection of pin sites

b) The pelvic hoop and pins initially resembled those described by DeWald and Ray (10) with four female attachments clamped to a hoop of rectangular cross section, which accommodated the extension bars (Fig 1) The pelvic pins were held in position on the hoop by four clamps

c) The extension bars were fixed proximally by socket head cap screws to the skull halo The bars were threaded over their distal ten to fifteen centimetres, and effective lengthening of the distance

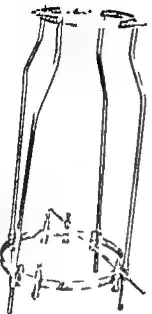

Figure 1 The Mark I halo pelvic apparatus

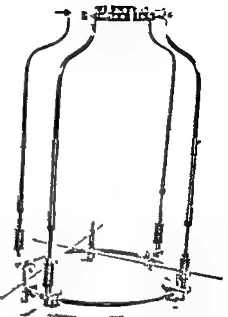

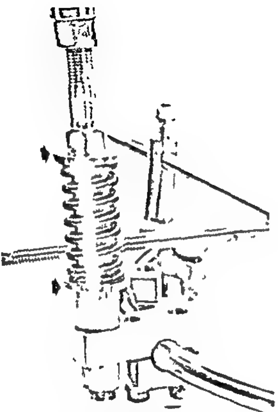

Figure 2 The Mark II halo-pelvic apparatus Note the multiple holes around circumference of the skull halo for alternative sites for placing the skull pins

jure 3 A detailed photograph of a compression spring at the base of an extension bar for measuring the forces The distance between the arrows is measured with a vernier caliper

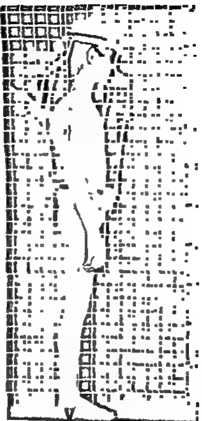

Figure 4 Lateral photograph of case 49, a twelve-year old patient with severe paralytic scoliosis A back winder is attached to the two posterior extension bars (arrow)

between the halo and hoop was achieved by winding the nut above the 'female' attachment down the thread on the extension bar (one millimetre thread)

Two difficulties arose with this Mark I design (Fig 1) Firstly, the extension bars protruding distally beyond the pelvic hoop made sitting difficult for the patient, as the two anterior extension bars abutted against the thighs Secondly, patients with pelvic obliquity presented particular difficulty with the fitting of the extension bars because of the rectangular cross sectional shape of the pelvic hoop

Modifications to the original design have been made to obviate the problem of the extension bars protruding beyond the pelvic hoop (Fig 2)(5) A threaded sleeve is now used instead of the original extension bar, which means that none of the extension bars extend beyond the hoop The pelvic hoop has been designed so that it is now round in cross section, making adjustment of the extension bars an easy matter, even when pelvic obliquity is extreme (Fig 3)

d) In October 1970, a force measuring system was designed to record the forces being applied to the spine (5) The four springs sit in sleeves at the base of the extension bars, and they are gradually compressed as the distraction progresses (Fig 3) Each spring has a stiffness of approximately 300 pounds per inch (5 4 kp/mm) The amount of spring deformation measured can be converted into a measurement of force from a standard table, thus providing a valuable guide line in managing the patients during distraction

e) An adjustable steel pressure pad which clamps to the posterior extension bars can be gradually applied against a kyphos or rib hump providing an additional local, corrective force Initial correction of a severe spinal curve is obtained by lengthening the spine, but in the latter stages of correction, a direct force applied at the apex of the deformity is desirable (Fig 13 b) Two points should be remembered if the back winder is used Firstly, a thick foam rubber disc must be interposed between the steel pad and the skin, as there is a high risk of pressure

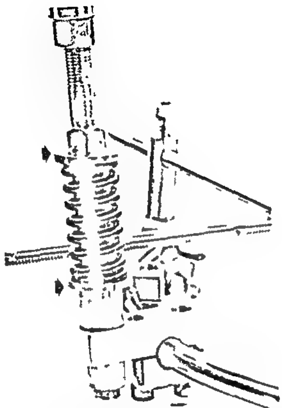

Figure 3 A detailed photograph of a compression spring at the base of an extension bar for measuring the forces The distance between the arrows is measured with a vernier caliper

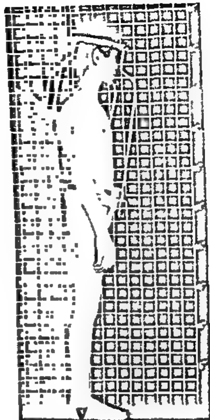

Figure 4 Lateral photograph of case 49, a twelve-year old patient with severe paralytic scoliosis A back winder is attached to the two posterior extension bars (arrow).

necrosis, particularly when an anterior oblique and a posterior vertical skin incision have been used in approaching the spine With this combination of incisions a large area of skin is rendered anaesthetic, and there is a high risk of developing ischaemic skin lesions by using the back winder Secondly, it must be removed from the posterior extension bars when force measurements are being taken

FITTING OF THE HALO-PELVIC APPARATUS

In the early months of experience with the halo-pelvic apparatus it was apparent that a drilling jig was essential for accurate insertion of the pelvic pins, in order to avoid the severe complications surrounding an inaccurate placement A drilling jig for arthrodesis of the hip (3) was easily modified for this purpose (Fig 5)

Major difficulties with several patients were encountered when the extension bars were applied at the same time as the skull halo, pelvic pins and hoop As a result, the fitting of the apparatus now entails two stages firstly, the skull halo, pelvic pins and hoop are fitted under general anaesthesia, secondly, several days later, the extension bars are applied to the pelvic hoop and skull halo with the patient awake and cooperating

General anaesthesia is required, although the skull halo itself can be fitted under local anaesthesia The patient's tolerance of this first anaesthesia is a fair indication of his ability to withstand subsequent anaesthesia for spinal operations Endo-tracheal anaesthesia is desirable because of the repeated alterations in position of the patient on the operating table

Perry has stressed that the skull halo must be placed below the greatest transverse diameter of the skull (52) The assistant may hold the patient s neck with the head extending beyond the end of the operating table, but, if the halo is to be used with any regularity, it is best to have a small thin metal extension to the table on which the patient's occiput can rest (44) The anterior pins are placed in the shallow fossae above the outer aspects of the eyebrows

The outer table of the skull is quite thick, and with the shouldering of the pins a secure purchase is obtained without excessive and dangerous penetration

The posterior points selected are above and approximately two centimetres behind the ear Several of the skull halos slipped off after distraction had commenced, and therefore it was felt that the use of supplementary skull pins would be advisable, particularly for the heavier and the long term patients If six pins are to be used, the extra two pins are placed approximately two centimetres behind the posterior ones (see Part IV)

The sterile skull halo is placed in position on the patient's scalp resting on his forehead, and the ideal holes in the halo are chosen for inserting the skull pins The pins are then tightened, making sure that the skull is in the centre of the halo when the pins are in the outer table of the skull, diametrically opposite pins should be tightened at the same time to ensure this After the pins have been tightened by finger pressure, a torque screw driver (Figs 5 and 6a) is then used, and the pins are driven into the outer table with a torque force of 5 5 pound inches (0 06 kpm) This procedure is completed by applying the outer locking nuts carefully to the outer extension of the skull pins, so that, when the nuts are tightened, the skull pin is not advanced any further This can be done by locking the pins with the screw driver

The patient s position is now changed he is moved down onto the middle of the table, and placed in the lateral position where the upward facing hemi-pelvis is prepared and draped (Fig 6b) This position is chosen for several reasons Firstly, it is easy to see the appropriate landmarks Secondly, the drilling jig is easily applied to the iliac crest with the patient in the lateral position A false sense of security should not exist at this stage, as the viscera do not fall away from the upper iliac crest There is a negative intraperitoneal pressure which prevents any gross movement of the peritoneal contents within the peritoneal cavity

The points for applying the drilling jig are now selected The anterior point for introducing the pin is on the iliac crest,

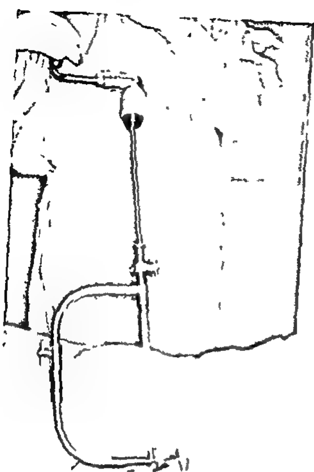

Figure 6 c The drilling jig in position and the pelvic pin inserted with a carpenter s brace

Figure 6 d The pelvic hoop being placed on the pelvic pins at the end of the operating table

continued until an equal length of pin is protruding anteriorly and posteriorly

It is important that the pin is felt to engage in the anterior part of the crest as it is very easy, particularly in thinner patients, for the pin to slide down the outer or the inner tables of the crest. Should this happen, the seating of the jig must be checked and a further incision attempted The pin, in the middle of its course through the crest, might be slightly within the pelvis (and it may be palpated here with the patient under anaesthesia)

One must beware of the peritoneum becoming wrapped around the pin at this time, this will be apparent as the anterior abdominal wall becomes sucked into the iliac fossa It is essential, should this happen, that the insertion be stopped and a second point chosen on the iliac crest for applying the pin

There will be no difficulties encountered at this stage with patients who have a normally developed pelvis However, in the much younger patients, and those with wasting of the pelvis associated with long standing paralysis and pelvic obliquity, the insertion of the pins may present problems If any difficulties are met or any anxiety felt about the precise placement of the pin, it is advisable to make a small incision just above the middle of the iliac crest and to place an exploratory finger within the iliac fossa, so that the direction of the pin, should it be intrapelvic, may be felt with accuracy, and the viscera pushed aside

It is important to note that the point of pin entry is not at the anterior spine but at some distance from it, and it is best, before applying the halo-pelvic apparatus to any patient, for the surgeon to examine a bony pelvis and check the relative positions of the landmarks recommended When a line is drawn connecting the anterior with the posterior superior spines, a pin crossing this gap will be almost totally within the iliac fossa with a great danger of bowel perforation

When the first pin has been placed in position, the skin wounds are sutured loosely around it, small dry dressings are applied to these

opposite the gluteal tubercle, "the tubercle of the crest", which may be as much as five centimetres upwards and posterior from the anterior superior iliac spine (Part IV, Fig. 42). It is readily palpated as the subcutaneous iliac crest is widest at this point. With this particular part of the crest grasped between the thumb and index finger a transverse incision is made down to the bone, or cartilage cap, of the crest, the length and depth of the incision depends on the amount of subcutaneous fat present.

The selected point of emergence is the posterior superior iliac spine, which is subcutaneous and easily identified by the overlying skin dimple, and a stab incision is made just medial to it.

The drilling jig is now applied, connecting these two landmarks It is important to have the points on the jig quite sharp so that they will penetrate the bony landmarks, the telescopic section of the jig ensures that one can use a good deal of hand pressure to push the points securely into bone, then the telescopic portion of the jig is tightened Ideally an assistant steadies the U-part of the jig whilst the pin is being inserted

For insertion of the pin, a carpenter's brace is used (Fig 6c) Power driven machinery for this purpose would be dangerous for, if any part of the pin is within the iliac fossa, it is likely to wrap the peritoneum around itself Apart from this, it is likely that with high speed drilling, a good deal of bone necrosis occurs (33) and this will merely increase the amount of discharge and probable infection around the pelvic pins

Preliminary tapping of the sharp drilling point of the pelvic pin through the cortex, or the cartilage cap of the crest of the ilium, is advisable, and the first few turns of the pin through the bone may be made with a Steinman pin holder Thereafter the carpenter's brace is attached to the end of the pin and, with slow rotation, the pin is advanced through the crest

Its emergence will be heard and felt by the pin rubbing against the sharp posterior part of the drilling jig At this point, the jig is detached from the crest, the brace is reattached, and the pin's route

complications For these reasons, it is wise to maintain the patient on close observation for 24 hours after fitting of the halo and the pelvic hoop

FITTING OF THE EXTENSION BARS

The fitting of the extension bars can take place when the patient has fully recovered from the general anaesthesia and the surgical procedure The patient is seated comfortably on a stool beneath a strong spring balance which is suspended from the ceiling (Fig 6e) The balance has attached to it a series of thin ropes and hooks which are hooked into four free holes of the skull halo A pulley system permits the patient to be drawn up, and this force is registered on the spring balance The patient should be suspended by the maximum amount of forc which is tolerable, comfortable and not producing neck pain This is often 25 per cent of the patient s body weight, but will obviously depend on many factors, particularly the thickness and strength of the patient s neck

With the patient in this semi-suspended position the four extension bars are affixed to the skull halo by the socket head cap screws, and to the pelvic hoop by the special clamp attachments If force measuring springs are used, they must be checked for stiffness before being placed in position All the fittings are tightened and the pulley with the spring balance can then be released

Distraction can commence several days after the fitting of the bars, prov ded that preliminary osteotomies are not required

DAY TO DAY MANAGEMENT OF THE PATIENT

The skull halo pins require little attention but they should be inspected each day and any discharge should be removed and cultured All skull pins are checked one week after fitting and tightened up again with the torque screw driver to 5 5 pound inches (0 06 kpm) If a patient experiences pain, it is due to looseness and the skull pin should be tightened, should it be associated with excessive

wounds, and the patient's position changed to the opposite lateral position on the table, which ideally is broken across its middle, thus allowing for the protrusion of this first pin

The patient may therefore need to be steadied by the assistant whilst the second pin is being inserted in an identical manner to the first

In those patients with pelvic obliquity, the pelvis on the higher side often has better muscles attached to it, and for this reason it is better developed, but its abnormal position increases the risk of perforation of the bowel

The patient s position is again changed to the supine position, the lower half of his body being supported by the assistant whilst the pelvic hoop is run over the lower limbs and, with the appropriate fittings, locked to the pelvic pins (Fig 6d) Whether the pelvic hoop be placed above or below the pins depends largely on how distally the spinal surgery will extend If fusion, be it anterior or posterior, is to include the lower lumbar spine, then it is advisable to place the pelvic hoop below the pelvic pins It is important for the locking attachments to be firmly tightened so that there is no movement of the pins, as this might produce pain and promote infection

POST-OPERATIVE MANAGEMENT

During post-operative management the patient is best nursed on a split mattress so that the posterior part of the pelvic hoop is accommodated within the split, and does not cause excessive pressure of the pelvic pins against the iliac crest

The skull halo pins may cause some headache which should be easily managed with salicylates Any excessive pain associated with the skull halo pins implies looseness of the fixation

Likewise, excessive pain associated with the pelvic pins may indicate their inaccurate insertion or looseness which will produce pain in the iliac crests Excessive and continuing pain may denote bleeding or an injury to the intestines, this will be discussed under

complications For these reasons, it is wise to maintain the patient on close observation for 24 hours after fitting of the halo and the pelvic hoop

FITTING OF THE EXTENSION BARS

The fitting of the extension bars can take place when the patient has fully recovered from the general anaesthesia and the surgical procedure The patient is seated comfortably on a stool beneath a strong spring balance which is suspended from the ceiling (Fig 6e). The balance has attached to it a series of thin ropes and hooks which are hooked into four free holes of the skull halo A pulley system permits the patient to be drawn up, and this force is registered on the spring balance The patient should be suspended by the maximum amount of force which is tolerable, comfortable and not producing neck pain This is often 25 per cent of the patient's body weight, but will obviously depend on many factors, particularly the thickness and strength of the patient s neck

With the patient in this semi-suspended position the four extension bars are affixed to the skull halo by the socket head cap screws, and to the pelvic hoop by the special clamp attachments If force measuring springs are used, they must be checked for stiffness before being placed in position All the fittings are tightened and the pulley with the spring balance can then be released

Distraction can commence several days after the fitting of the bars, provided that preliminary osteotomies are not required

DAY TO DAY MANAGEMENT OF THE PATIENT

The skull halo pins require little attention but they should be inspected each day and any discharge should be removed and cultured All skull pins are checked one week after fitting and tightened up again with the torque screw driver to 5.5 pound inches (0.06 kpm). If a patient experiences pain, it is due to looseness and the skull pin should be tightened, should it be associated with excessive

wounds, and the patient's position changed to the opposite lateral position on the table, which ideally is broken across its middle, thus allowing for the protrusion of this first pin

The patient may therefore need to be steadied by the assistant whilst the second pin is being inserted in an identical manner to the first.

In those patients with pelvic obliquity, the pelvis on the higher side often has better muscles attached to it, and for this reason it is better developed, but its abnormal position increases the risk of perforation of the bowel

The patient's position is again changed to the supine position, the lower half of his body being supported by the assistant whilst the pelvic hoop is run over the lower limbs and, with the appropriate fittings, locked to the pelvic pins (Fig 6d) Whether the pelvic hoop be placed above or below the pins depends largely on how distally the spinal surgery will extend If fusion, be it anterior or posterior, is to include the lower lumbar spine, then it is advisable to place the pelvic hoop below the pelvic pins It is important for the locking attachments to be firmly tightened so that there is no movement of the pins, as this might produce pain and promote infection

POST-OPERATIVE MANAGEMENT

During post-operative management the patient is best nursed on a split mattress so that the posterior part of the pelvic hoop is accommodated within the split, and does not cause excessive pressure of the pelvic pins against the iliac crest

The skull halo pins may cause some headache which should be easily managed with salicylates. Any excessive pain associated with the skull halo pins implies looseness of the fixation.

Likewise, excessive pain associated with the pelvic pins may indicate their inaccurate insertion or looseness which will produce pain in the iliac crests. Excessive and continuing pain may denote bleeding or an injury to the intestines, this will be discussed under

a) *Myelography* is essential to exclude any intraspinal lesion not detectable with normal routine radiography, or to define the extent of an internal kyphosis with cord compression If there is a lesion present *in the spinal canal*, such as diastematomyelia or an intrathecal lipoma, then a strong corrective force applied to the spine is very likely to produce a paraplegia

b) Respiratory function tests are essential and are *used routinely* They should always be mandatory in the operative treatment of scoliosis especially in severe paralytic curves There is the possibility of a traction injury to the vagus nerve, which will produce loss of the cough impulse and sputum retention The sequelae of such a complication would be difficult to assess if base line respiratory studies had not been done

Incorrect fitting of the apparatus

The patient should be relatively comfortable after the fitting of the halo and the hoop, and if there is any undue pain it suggests that there is something wrong If the skull halo has been firmly fixed, then there should be no more than discomfort associated with the skull pins, if they have been placed in the proper positions One cause of intense pain has been placing one of the anterior pins too medially, near or through a supraorbital nerve

Familiarity with the *proper siting for placement of* the skull pins is important *One must bear in mind the anatomy of the cutaneous nerves of the scalp* in the region of the eyebrows and the ears, as their irritation with a skull pin produces intense pain

Patients with meningomyelocele may have had a Spitz-Holter valve in position, usually above and behind one ear If the halo is to be used, the pins on the same side as the valve must be placed at some distance from it and its catheter, *so as to avoid* problems

The pelvic pins, if firmly embedded in the iliac crests *and locked* tightly to the pelvic hoop, should *not cause anything more than* discomfort If there is *pain* about the site of entry, *or exit*, of one

discharge, then that pin should be changed The multiple holes in the skull halo permit these changes of pin without any difficulty

The pelvic pin sites likewise are examined daily and kept covered with small dry dressings, any discharge should be cultured and the appropriate antibiotic used

As regards keeping the patients in bed, it has been customary to confine them to bed only when they are recovering from surgery or are suffering from excessive pain and/or discharge from their pelvic pin sites

The most important single factor in avoiding infection associated with the skull and pelvic pins is that they must have rigid fixation in bone Whilst they are firmly fixed in bone, there is only a very slight likelihood of infection Once looseness develops, infection becomes almost an automatic sequela

PITFALLS AND GUIDELINES IN USING THE HALO PELVIC APPARATUS

Selection of the patient

Halo-pelvic traction should be reserved for those patients whose spinal deformities cannot be well corrected by other methods of treatment currently available In Hong Kong, the main indications for the use of the technique have been tuberculous kyphosis (40) and paralytic scoliosis (30%) After more than five years experience with halo-pelvic traction, the indications have altered a little but precise indications cannot yet be categorically stated For those patients with severe scoliosis and severe respiratory insufficiency and those with kyphotic deformities, the halo-pelvic apparatus has, in our hands, remained the mainstay of management

Faulty preparation of the patient

Any patient whose deformity is severe enough to require treatment with the halo-pelvic apparatus should have

a) myelography before surgery and
b) adequate preliminary respiratory function tests

a) Myelography is essential to exclude any intraspinal lesion not detectable with normal routine radiography, or to define the extent of an internal kyphosis with cord compression If there is a lesion present in the spinal canal, such as diasteratomyelia or an intrathecal lipoma, then a strong corrective force applied to the spine is very likely to produce a paraplegia

b) Respiratory function tests are essential and are used routinely They should always be mandatory in the operative treatment of scoliosis especially in severe paralytic curves There is the possibility of a traction injury to the vagus nerve, which will produce loss of the cough impulse and sputum retention The sequelae of such a complication would be difficult to assess if base line respiratory studies had not been done

Incorrect fitting of the apparatus

The patient should be relatively comfortable after the fitting of the halo and the hoop, and if there is any undue pain it suggests that there is something wrong If the skull halo has been firmly fixed, then there should be no more than discomfort associated with the skull pins, if they have been placed in the proper positions One cause of intense pain has been placing one of the anterior pins too medially, near or through a supraorbital nerve

Familiarity with the proper siting for placement of the skull pins is important One must bear in mind the anatomy of the cutaneous nerves of the scalp in the region of the eyebrows and the ears, as their irritation with a skull pin produces intense pain

Patients with meningomyelocele may have had a Spitz-Holter valve in position, usually above and behind one ear If the halo is to be used, the pins on the same side as the valve must be placed at some distance from it and its catheter, so as to avoid problems

The pelvic pins, if firmly embedded in the iliac crests and locked tightly to the pelvic hoop, should not cause anything more than discomfort If there is pain about the site of entry, or exit, of one

of the pelvic pins, then a check should be made to see that skin is not excessively tented about a pin This can present problems, as an area of necrotic skin will develop, with sloughing and inevitable infection

In the first 24-hour-period after the fitting of the halo and the pelvic hoop the patient should be kept under routine observation, and if there are any difficulties, such as rising pulse, increasing temperature, or abdominal pain, then a general surgeon should be consulted, particularly if there is any possibility of one of the pins being intrapelvic

The importance of accurate placement of the pelvic pins cannot be over-emphasised To the author s knowledge there have been four instances of damage to the peritoneum or the intestines with incorrect insertion of the pelvic pins Our experience with laceration of the peritoneum is referred to later (Part II, Chapter II) Three instances occurring in other clinics included a) injury to the outer layer of sigmoid colon, detected post mortem in a patient who died from other causes after surgery, b) perforation of the sigmoid colon, and c) one patient who sustained perforation of both the sigmoid colon and the caecum with the two pins

This particular sequence has been developed because of its safety for the patient Points to be re-emphasised are

1) A drilling jig must be used for safe, accurate insertion of the pelvic pins

2) A power drill is contraindicated for this procedure It is dangerous and likely to produce a potentially fatal bowel injury A carpenter's brace is recommended as it is simple, safe, and if used slowly, is least likely to cause bone necrosis

3) The lateral position of the patient is selected because it is the easiest position in which to apply the drilling jig, to see all the bony landmarks at one time, and for the surgeon to position himself when doing the instrumentation

4) The extension bars are not put on the patient while he is under anaesthesia It is preferable and advisable to apply them several days later

Complications likely to occur during distraction of the patient

The most common faults are acute distraction of the cervical spine, and cranial nerve injuries To avoid these problems there are four basic guide lines which must be used during distraction They are

A) Regular clinical observation

B) Daily neurological assessment.

C) Regular lateral radiographs of the cervical spine

D) The use of force measurements

A Regular clinical observation

Any complaint which the patient makes during distraction must be dealt with immediately In this respect the nursing and paramedical staff must be given encouragement and responsibility in the management of these patients It is wise to include them in the general teaching programme, so that they are familiar with the apparatus and its use and know how to release the tension in the extension bars should the patient complain of pain or disability The most common complaint during distraction is of neck pain, and one must not continue distraction until this has settled If neck pain persists, then the extension bars should be shortened by several turns until the patient is comfortable again

Nursing care includes daily inspection of the skull halo and the pelvic pin sites, and any change in their state, discharge, pain or looseness, must be reported to the surgeon in charge

B Neurological assessment

A daily neurological assessment of each patient must be made during active distraction For this purpose a basic chart (Table 1) has been developed which permits a rapid check of the nerves at risk

If a nerve injury occurs or if the patient notices some weakness, the extension bars must be shortened immediately, as the time for recovery of the nerve injury, which is usually a neurapraxia, will depend on how long the nerve has been over-stretched The quicker the tension is released the faster will be the return of nerve function

TABLE 1

BASIC NEUROLOGICAL EXAMINATION FOR PATIENTS UNDERGOING DISTRACTION

A. Spinal cord

Questions

1) Any weakness in the legs?
2) Any numbness in the legs?
3) Any loss of bladder function?

Tests

1) Up or down going toes?
2) Any clonus of ankles or knees?

B. Cranial nerves (Tests for VI, IX, X, XII)

Questions

1) Any double vision?
2) Any difficulty swallowing?
3) Difficulty coughing?
4) Any change in voice?
5) Any tongue weakness?

Tests

1) Eye movements (VI)
2) Palate reflex (IX)
3) Explosive cough (X)
4) Quality of speech, nasal? (IX or X)
5) Extend tongue, is it midline? (XII)

C. Upper limbs

Questions

1) Difficulty in moving hand, arm, or shoulder joint?
2) Any numbness or weakness of the hand?

Tests

1) Abduct the shoulder (C5, 6)
2) Flex the forearm (C5, 6)
3) Test grip of hand
4) Test sensation of finger tips (C6-T1)

C Lateral radiographs of the cervical spine

The upper cervical spine, because of its relative frailty, is the most susceptible region of the spine to over distraction For this reason regular lateral radiographs of the cervical spine are mandatory They should be taken with the patient at a fixed distance from the x-ray plate, so that measurements of films will be comparable

D The use of force measurements

The use of a force measuring system is most important It provides an indication of the amount and rate at which the stress on the spine is being built up From studies of the pathological changes in the cervical spine with distraction, it is apparent that when forces measuring over 60 per cent of the body weight are applied, the complication rate becomes significantly higher (Part II, Chapter II) By having force measurements available, these complications can be minimised Some patients have flexible curves, such as those with long paralytic C-curves, while others, like patients with tuberculous kyphosis, have more rigid deformities The rigidity of the curves differs enormously from patient to patient and depends mainly on their etiology The force measurements provide the information necessary to avoid building up dangerously high forces too rapidly and this is most important in the rigid deformities

Removing the halo-pelvic apparatus

The actual removal of the apparatus is relatively simple, deciding when to remove it may occasionally present problems

The precise procedure will depend on the deformity and the method which has been used to correct and fuse it It will also depend to a large extent on the internal fixation used and its stability The most common deformity will be a scoliosis and the most common instrument the Harrington rod, it must be remembered that after several weeks in the halo-pelvic apparatus, there is quite significant osteoporosis and the Harrington hooks are more likely to cut through the softened bone if the spine is suddenly released It is for this reason that often the extension bars are shortened by 1 or 2 millimetres each day so as to gradually load the rod and place some stress through the fusion mass If there is any slipping of

TABLE 1

1) Difficulty in moving hand, arm, or shoulder joint?

2) Any numbness or weakness of the hand?

Tests

1) Abduct the shoulder (C5, 6)

2) Flex the forearm (C5, 6)

3) Test grip of hand

4) Test sensation of finger tips (C6-T1)

protective sensation Failing to do this results in a high incidence of pressure sores

Inaccurate timing in the removal of the halo-pelvic apparatus

One error is to remove the halo-pelvic apparatus too early, which may result in a significant loss of some of the correction obtained When internal fixation is possible (usually the Harrington rod), it should be used at the time of posterior fusion, and the traction in the halo-pelvic apparatus should be maintained for a further four to six weeks The rod can then be gradually loaded by a slight daily shortening of the extension bars, as rapid release is likely to produce compression fractures of the osteoporotic, posterior elements by the hooks

This phenomenon is of relatively minor importance compared to the great advantages of the apparatus for patients with spinal deformities and respiratory crippling In such cases, consideration should be given to internal fixation when appropriate, and to the removal of the apparatus when a body jacket could be considered as a reasonable alternative

SUMMARY

The history of the development of the halo-pelvic apparatus has been described as has the apparatus together with various modifications and improvements which have been made over the years

A detailed account of the fitting of the halo pelvic apparatus is presented with particular emphasis on several safety factors which include

1) The use of a drilling jig and the anatomical landmarks chosen in the iliac crests

2) Placing the patient in a lateral position on the operating table during insertion of the pelvic pins

3) Fitting the extension bars at a later stage with the patient awake and co operating

the implants at this stage, it will be noticed by the patient and check radiographs should be done forthwith

When the patient has been in the apparatus for some months, large holes will have developed in the crests where the pelvic pins have sawn away the bone with which they are in contact When the extension bars are slackened a little, these are likely to become even more mobile and therefore painful This will often force the surgeon to remove the apparatus a little sooner than he may have anticipated

The actual removal of the apparatus is quite straightforward Under general anaesthesia, the extension bars are removed Next the skull pins are removed from the skull and the halo, being particularly careful to cover the eyes which are at risk Now the pelvic pins are removed using a carpenter s brace They can be removed either from the front or back, the length of pin which has been protruding is prepared with iodine solution before extracting it from the iliac crest

The opened wounds are covered with small dry dressings and these invariably heal within a week

Should there be some concern about the internal fixation or maintaining the correction that has been achieved with the halo-pelvic apparatus, it is possible to apply almost an entire body jacket with the patient still in the halo-pelvic apparatus Proximally, the cast can be moulded up to the manubrium sterni and posteriorly to the base of the neck, this may be extended proximally to include the neck when the apparatus has been removed Distally it can be extended down around the pelvic pins to embrace the pelvis so that the pins can be removed and the pelvic portion of the plaster then completed

Windows of an appropriate size may then be removed from the pelvic portion of the body jacket to dress the skin wounds which heal rapidly Attention should be given to the pressure on anaesthetic skin over the back if an oblique thoracotomy incision has been combined with a midline posterior vertical incision In such cases, it is routine to remove that area of plaster which impinges against skin devoid of

protective sensation. Failing to do this results in a high incidence of pressure sores

Inaccurate timing in the removal of the halo-pelvic apparatus

One error is to remove the halo-pelvic apparatus too early, which may result in a significant loss of some of the correction obtained. When internal fixation is possible (usually the Harrington rod), it should be used at the time of posterior fusion, and the traction in the halo-pelvic apparatus should be maintained for a further four to six weeks. The rod can then be gradually loaded by a slight daily shortening of the extension bars, as rapid release is likely to produce compression fractures of the osteoporotic, posterior elements by the hooks

This phenomenon is of relatively minor importance compared to the great advantages of the apparatus for patients with spinal deformities and respiratory crippling. In such cases, consideration should be given to internal fixation when appropriate, and to the removal of the apparatus when a body jacket could be considered as a reasonable alternative

PART II

CLINICAL INFORMATION - TREATMENT, RESULTS AND COMPLICATIONS

Pitfalls and guidelines in using the halo-pelvic apparatus are described with emphasis on the correct selection of the patient and with particular attention directed towards avoiding complications during the use of the halo-pelvic apparatus.

CHAPTER I CLINICAL MATERIAL, METHODS OF TREATMENT AND RESULTS

INTRODUCTION

104 consecutive unselected patients with severe spinal deformities have been treated with the halo pelvic apparatus at the Duchess of Kent Children's Orthopaedic Hospital and Convalescent Home, Sandy Bay, Hong Kong, over a 3 5 year period from January 1969 to August 1972

Age and sex

The average age of the patients was 15 years (range 3 to 26 years) 47 patients (45 per cent) were males Their average age was 14 7 years (range 3 to 23 years) 57 patients (55 per cent) were females Their average age at the beginning of treatment was 15 2 years (range 5 to 26 years)

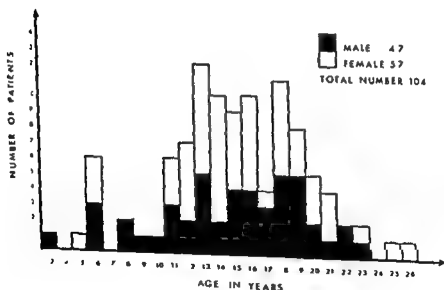

Figure 7 Barograph to show the age and sex of 104 patients

average tire is an indication of both the severity and the rigidity of the deformities as well as the associated respiratory insufficiency from which these patients suffer

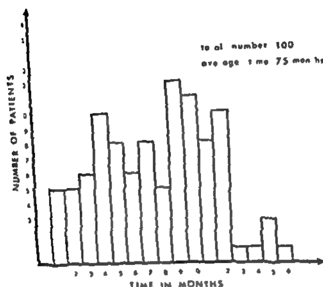

Figure 8 Barograph to demonstrate the length of tire patients spent in the halo pelvic apparatus

HALO PELVIC APPARATUS AS EXTERNAL FIXATION OR AS A CORRECTING INSTRUMENT

Whilst most patients had halo pelvic distraction to correct major spinal deformities, in sore (cases 28, 73, 89, 90, 103) the apparatus was used mainly as a means of external spine fixation so as to provide stability in situations where the spine was particularly unstable There were also several patients where maximum distraction was not attempted because of the potential risk to the spinal cord, however, stability was provided by the apparatus and slight, careful distraction was allowed

Etiology of deformity

The etiology of the patients' deformities was

1 Tuberculous kyphosis There were 42 patients with tuberculous kyphotic deformities (40 per cent) of which 25 were males and 17 were females Their average age at the commencement of treatment was 16 1 years (range 3 to 26 years)

2 Paralytic scoliosis 31 patients had severe paralytic scoliosis (30 per cent) 15 were males, 16 were females and the average age was 14 1 years (range 6 to 25 years)

3 Idiopathic scoliosis 15 patients (14 per cent) had severe idiopathic scoliosis There were 14 females and 1 male patient, and their average age was 15 6 years (range 6 to 21 years)

4 Congenital kyphoscoliosis 10 patients with congenital kyphoscoliosis (10 per cent), included 4 males and 6 females Their average age at the beginning of treatment was 12 8 years (range 6 to 19 years)

5 Neurofibromatosis kyphoscoliosis : 6 patients had deformities due to neurofibromatosis (6 per cent), 2 males and 4 females, and their average age was 13 8 years (range 10 to 19 years)

6 Salvage group A separate study was made of the 8 scoliosis patients (paralytic - 4 patients, idiopathic 4 patients) with previous posterior spinal fusions requiring osteotomies before correction and revision of the fusion

There were four deaths during treatment (cases 40, 41, 42, 96) Three were patients with severe tuberculous kyphosis and one had a severe congenital scoliosis Each of these patients died shortly after major spinal surgery and they will be referred to later All four patients had gross, fixed, spinal deformities associated with severe respiratory insufficiency

The average time a patient spent in the halo-pelvic apparatus was 7 5 months (range 1 to 16 months)(Fig 8) The most common period of time in the apparatus was 9 months (12 patients) This long

Extent and degree of deformity

The average number of vertebrae destroyed by the tuberculous process was 6 (range 3 to 9 vertebrae) (Fig 11)

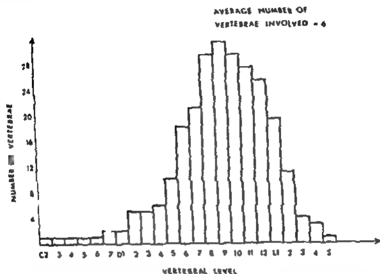

Figure 11 : Barograph demonstrating the level and number of vertebrae destroyed by tuberculous disease process The average number of vertebrae involved per patient was 6

The vertebral body most commonly destroyed was the 9th thoracic vertebra The average angle of kyphosis measured 117 degrees (range 59 to 147 degrees)

Previous surgery

There were 11 patients who had had previous surgery for their tuberculous disease This surgery included fusions in all but two cases where debridements alone were done

Cord compression

16 patients had clinical evidence of cord compression before surgery All had significant narrowing of the spinal canal, best demonstrated

Introduction

There were 42 patients with tuberculous kyphosis, three of these patients died during treatment In one of the remaining 39 patients the apparatus was used as external spine fixation rather than as a correcting instrument There were 25 males (average age 16 0 years) and 17 females (average age 16 3 years) (Fig 9) Their average time in the halo-pelvic apparatus was 8 4 months with a range of 1 to 16 months (Fig 10) The average length of follow-up for this group of patients was 2 9 years

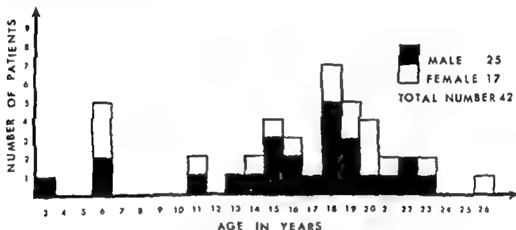

Figure 9 Tuberculous kyphosis : Barograph showing the age and sex of patients

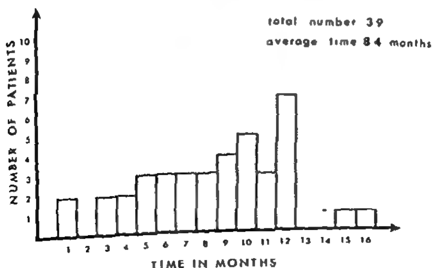

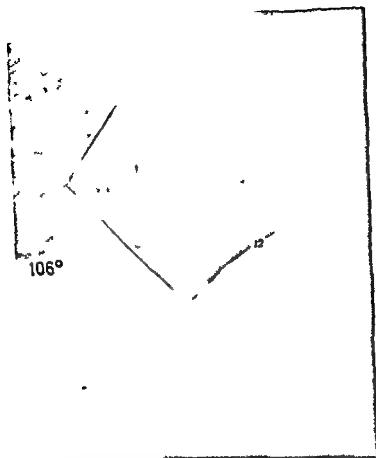

Figure 10 Tuberculous kyphosis Barograph showing the length of time spent in the halo-pelvic apparatus

F g re 12 Case 1 A lateral myelogram in tuberculous kyphosis to demonstrate the acute angulation of the spinal canal and its narrowing at the level of the internal kyphos This knuckle of bone must be removed before safe distraction can be undertaken

the implants at this stage, it will be noticed by the patient and check radiographs should be done forthwith

When the patient has been in the apparatus for some months, large holes will have developed in the crests where the pelvic pins have sawn away the bone with which they are in contact When the extension bars are slackened a little, these are likely to become even more mobile and therefore painful This will often force the surgeon to remove the apparatus a little sooner than he may have anticipated

The actual removal of the apparatus is quite straightforward Under *general anaesthesia, the extension bars are removed Next the skull* pins are removed from the skull and the halo, being particularly careful to cover the eyes which are at risk Now the pelvic pins are removed using a carpenter's brace They can be removed either from the front or back, the length of pin which has been protruding is prepared with iodine solution before extracting it from the iliac crest

The opened wounds are covered with small dry dressings and these invariably heal within a week

Should there be some concern about the internal fixation or maintaining the correction that has been achieved with the halo-pelvic apparatus, it is possible to apply almost an entire body jacket with the patient still in the halo-pelvic apparatus Proximally, the cast can be moulded up to the manubrium sterni and posteriorly to the base of the neck, this may be extended proximally to include the neck when the apparatus has been removed Distally it can be extended down around the pelvic pins to embrace the pelvis so that the pins can be removed and the pelvic portion of the plaster then completed

Windows of an appropriate size may then be removed from the pelvic portion of the body jacket to dress the skin wounds which heal rapidly Attention should be given to the pressure on anaesthetic skin over the back if an oblique thoracotomy incision has been combined with a midline posterior vertical incision In such cases, it is routine to remove that area of plaster which impinges against skin devoid of

protective sensation. Failing to do this results in a high incidence of pressure sores.

Inaccurate timing in the removal of the halo-pelvic apparatus

One error is to remove the halo-pelvic apparatus too early, which may result in a significant loss of some of the correction obtained. When internal fixation is possible (usually the Harrington rod), it should be used at the time of posterior fusion, and the traction in the halo-pelvic apparatus should be maintained for a further four to six weeks. The rod can then be gradually loaded by a slight daily shortening of the extension bars, as rapid release is likely to produce compression fractures of the osteoporotic, posterior elements by the hooks

This phenomenon is of relatively minor importance compared to the great advantages of the apparatus for patients with spinal deformities and respiratory crippling In such cases, consideration should be given to internal fixation when appropriate, and to the removal of the apparatus when a body jacket could be considered as a reasonable alternative

SUMMARY

The history of the development of the halo-pelvic apparatus has been described as has the apparatus together with various modifications and improvements which have been made over the years

A detailed account of the fitting of the halo-pelvic apparatus is presented with particular emphasis on several safety factors which include

1) The use of a drilling jig and the anatomical landmarks chosen in the iliac crests

2) Placing the patient in a lateral position on the operating table during insertion of the pelvic pins

3) Fitting the extension bars at a later stage with the patient awake and co-operating

by myelography (Fig 12)

The degree of cord compression varied clinically from slight spasticity in the lower limbs in most patients, to the more extreme variety, with marked spasticity, severe clonus of knee and ankle and walking being difficult, if not impossible This latter group represents the usual manifestations of penetration of the cord by the tuberculous disease process (28)

METHOD OF TREATMENT

The general plan of treatment in these patients was to decompress the spinal cord by removing the internal kyphos and, following gradual correction over some weeks with halo-pelvic distraction, to perform anterior and posterior fusions (64)

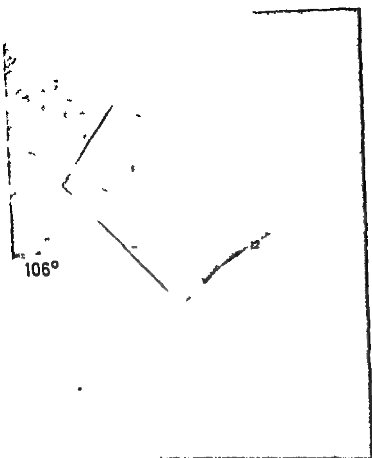
Chemotherapy

The routine treatment included the standard anti-tuberculous drugs, even for those patients with apparently healed spine disease The drugs were continued for up to 18 months Reactivation of infection in several earlier patients after surgery has now made the inclusion of the appropriate drug therapy routine

Planning the operations

The sequence of operations, while conforming to a basic pattern, was varied according to the needs of each individual patient This entailed mobilisation of the deformity and simultaneous cord decompression by removing the internal kyphos, gradual correction and then fusions This planning depended on the site and extent of the kyphos and the respiratory reserve of the patient

Four separate combinations of mobilising osteotomies and fusions were employed



A One stage osteotomy Three quarter circumferential osteotomy

This ent

1 Remo kyphos and half the (usu ntane

METHOD OF TREATMENT

The general plan of treatment in these patients was to decompress the spinal cord by removing the internal kyphos and, following gradual correction over some weeks with halo-pelvic distraction, to perform anterior and posterior fusions (64)

Chemotherapy

The routine treatment included the standard anti-tuberculous drugs, even for those patients with apparently healed spine disease The drugs were continued for up to 18 months Reactivation of infection in several earlier patients after surgery has now made the inclusion of the appropriate drug therapy routine

Planning the operations

The sequence of operations, while conforming to a basic pattern, was varied according to the needs of each individual patient This entailed mobilisation of the deformity and simultaneous cord decompression by removing the internal kyphos, gradual correction and then fusions This planning depended on the site and extent of the kyphos and the respiratory reserve of the patient

Four separate combinations of mobilising osteotomies and fusions were employed

A One stage osteotomy - Three-quarter circumferential osteotomy

This entailed

1 Removal of the internal kyphos and half the (usually) spontaneously fused posterior elements at the same sit

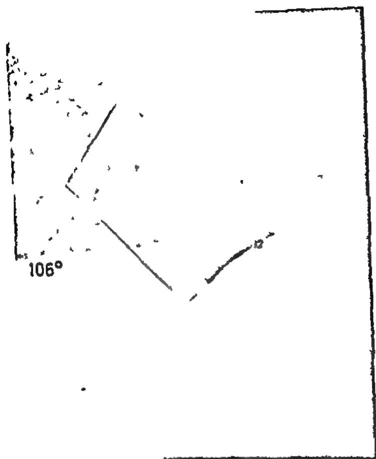

Figure 12 Case 1 A lateral myelogram in tuberculous kyphosis to demonstrate the acute angulation of the spinal canal and its narrowing at the level of the internal kyphos This knuckle of bone must be removed before safe distraction can be undertaken

2. Following maximal distraction, posterior fusion.

3. Anterior fusion.

B Two stage osteotomies

This included

1. Removal of the internal kyphos followed by distraction.

2. Posterior osteotomy, after which further distraction

3. Posterior fusion

4. Anterior fusion. The biggest single drawback to this sequence is that it involves four major operations.

C. Combined posterior osteotomies and fusion

This sequence is essentially the same as (B), except that the posterior osteotomies and fusions are included at the one sitting (Figs 13 a, b, c). The three stages therefore include:

1. Removal of the internal kyphos via the usual anterior approach.

2. Posterior osteotomies and extensive fusion and, when maximal distraction has been achieved,

3. anterior fusion (Fig. 13 c).

D. Extrapleural costotransversectomy approach

The internal kyphos may be removed from in front of the spinal cord by an extrapleural costotransversectomy approach (5 cases) This must be considered for those patients with severe respiratory insufficiency and kyphoses which are either very deep or else situated in the cervico dorsal spine Because of severe respiratory impairment, two of these patients required elective pre-operative tracheostomy

A complete circumferential osteotomy in one operation is not advisable because, apart from danger to the cord and its blood supply, the subsequent distraction will merely pull the limbs of the kyphos apart without necessarily improving the angle of the deformity A thin bridge of bone must initially connect the limbs of the kyphos so that distraction will hinge the kyphos open.

Figure 13 a Pre operative tracing Correction requires forces applied in the direction shown by arrows

Figure 13 b Tracing towards completion of distraction Corrective force is now applied over the external kyphos (arrow)

Figure 13 c Tracing after anterior (a) and posterior (p) fusions Note extent of posterior fusions (arrows and bulk of anterior bone graft

Figure 13 Case 23 Tuberculous kyphosis Tracings of lateral radiographs before, during and after surgery

2. Following maximal distraction, posterior fusion.

3. Anterior fusion.

II Two stage osteotomies

This included.

1. Removal of the internal kyphos followed by distraction.

2. Posterior osteotomy, after which further distraction.

3. Posterior fusion.

4. Anterior fusion. The biggest single drawback to this sequence is that it involves four major operations.

C. Combined posterior osteotomies and fusion

This sequence is essentially the same as (B), except that the posterior osteotomies and fusions are included at the one sitting (Figs. 13 a, b, c). The three stages therefore include:

1. Removal of the internal kyphos via the usual anterior approach.

2. Posterior osteotomies and extensive fusion and, when maximal distraction has been achieved,

3. anterior fusion (Fig 13 c).

D. Extrapleural costotransversectomy approach

The internal kyphos may be removed from in front of the spinal cord by an extrapleural costotransversectomy approach (5 cases) This must be considered for those patients with severe respiratory insufficiency and kyphoses which are either very deep or else situated in the cervico dorsal spine. Because of severe respiratory impairment, two of these patients required elective pre-operative tracheostomy

A complete circumferential osteotomy in one operation is not advisable because, apart from danger to the cord and its blood supply, the subsequent distraction will merely pull the limbs of the kyphos apart without necessarily improving the angle of the deformity A thin bridge of bone must initially connect the limbs of the kyphos so that distraction will hinge the kyphos open.

Figure 13 a Pre operative tracing Correction requires forces applied in the direction shown by arrows

Figure 13 b Tracing towards completion of distraction Corrective force is now applied over the external kyphos (arrow)

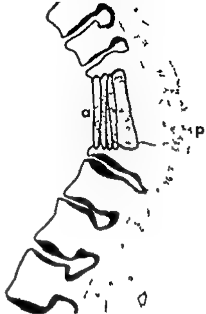

Figure 13 c Tracing after anterior (a) and posterior (p) fusions Note extent of posterior fusions (arrows) and bulk of anterior bone graft

Figure 13 Case 23 Tuberculous kyphosis Tracings of lateral radiographs before, during and after surgery *Technique* used was method of treatment (c), see text

2. Following maximal distraction, posterior fusion.

3. Anterior fusion.

B. Two stage osteotomies

This included:

1. Removal of the internal kyphos followed by distraction.

2. Posterior osteotomy, after which further distraction

3. Posterior fusion.

4. Anterior fusion. The biggest single drawback to this sequence is that it involves four major operations.

C. Combined posterior osteotomies and fusion

This sequence is essentially the same as (B), except that the posterior osteotomies and fusions are included at the one sitting (Figs 13 a, b, c) The three stages therefore include:

1. Removal of the internal kyphos via the usual anterior approach.

2. Posterior osteotomies and extensive fusion and, when maximal distraction has been achieved,

3. anterior fusion (Fig. 13 c).

D. Extrapleural costotransversectomy approach

The internal kyphos may be removed from in front of the spinal cord by an extrapleural costotransversectomy approach (5 cases) This must be considered for those patients with severe respiratory insufficiency and kyphoses which are either very deep or else situated in the cervico dorsal spine Because of severe respiratory impairment, two of these patients required elective pre-operative tracheostomy

A complete circumferential osteotomy in one operation is not advisable because, apart from danger to the cord and its blood supply, the subsequent distraction will merely pull the limbs of the kyphos apart without necessarily improving the angle of the deformity A thin bridge of bone must initially connect the limbs of the kyphos so that distraction will hinge the kyphos open.

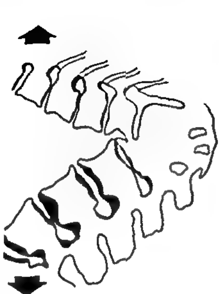

Figure 13 a *Pre* operative tracing Correction requires forces applied in the direction shown by *arrows*

Figure 13 b Tracing towards completion of distraction *Corrective force* is now applied over the external kyphos (arrow)

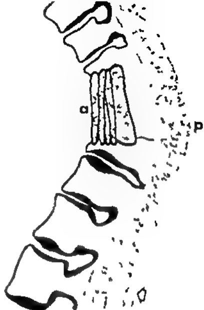

Figure 13 c Tracing after anterior (a) and posterior (p) fusions Note extent of posterior fusions (*arrows*) and bulk of anterior bone graft

Figure 13 *Case 23* - Tuberculous kyphosis Tracings of lateral radiographs before, during and after surgery Technique used was method of *treatment* (c), see text

No osteotomies were performed in five patients (cases 14, 22, 25, 30, 32), as they had relatively mobile and less marked deformities associated with active disease in the spine (their average age was 7 years) Following very carefully supervised distraction they subsequently had anterior and posterior fusions

A one-staged osteotomy was used in 12 patients and a two-stage osteotomy in 20 patients 6 of these 20 patients had combined posterior osteotomies and fusions Two patients required revision of the osteotomies in order to mobilise the deformities sufficiently for distraction to be effective

Two patients had an anterior spinal fusion alone (cases 3, 6), the remaining patients had anterior and posterior fusions In several cases the latter was done when loss of correction had already occurred In order to maintain the correction achieved, a double fusion is mandatory, especially in those patients with severe deformities

Post-operative management

Following the last operation, the patients were maintained in the halo-pelvic apparatus until the grafts had consolidated Initially this period of time was usually up to 6 months, but it has been reduced more recently because of the higher incidence of cervical spine complications associated with prolonged immobilisation Following removal of the halo-pelvic apparatus under general anaesthesia the patients remained in bed for one week, until the pin site wounds had healed and a full length body cast was applied to provide a total period of immobilisation of twelve months

RESULTS - TUBERCULOUS KYPHOSIS (Table 2)

Of the 42 patients, 3 died as a result of surgery, 2 had the apparatus removed early and in one case, it was used as a holding device The remaining 36 patients were followed for an average of 2 9 years (range 1 25 to 4 5 years)

TABLE 2

TUBERCULOUS KYPHOSIS

Case number	Pre-op degree (average)	Maximum correction Average	As a	Follow-up Correction (average)	Length of time in years
1 to 10	117°	to 80° (Corr of 37°)	32.	93° (Loss of 13°)	3 9
11 to 20	114°	to 70° (Corr of 44°)	39	77° (Loss of 7°)	3 1
21 to 27	106°	to 73° (Corr of 33°)	32	76° (Loss of 3°)	2 5
31 to 39	128°	to 101° (Corr of 27°)	22	104° (Loss of 3°)	1 7
Total number of patients 36	117°	to 81° (Corr of 36°)	31	88° (Loss of 7°)	2 9

There were no figures to indicate that deformities more proximal in the spine achieved better correction, because the variables were so great age, activity of disease and previous surgery, etc From a mechanical point of view, however, it is apparent that the more proximal regions in the spine have greater forces applied in the halo pelvic apparatus and the clinical impression is that the younger the patient, the more active and the more recent and the more proximal the disease, the greater the correction with the halo pelvic apparatus

The average pre operative angle of kyphosis was 117 degrees and after correction and fusion the average angle was 81 degrees representing a correction of 36 degrees (or 31 per cent) As most deformities were in the thoracic spine, where the normal kyphosis measures from 20 to 40 degrees (54), this correction is in fact better than it would seem from the angular measurements alone At

No osteotomies were performed in five patients (cases 14, 22, 25, 30, 32), as they had relatively mobile and less marked deformities associated with active disease in the spine (their average age was 7 years) Following very carefully supervised distraction they subsequently had anterior and posterior fusions

A one-staged osteotomy was used in 12 patients and a two-stage osteotomy in 20 patients 6 of these 20 patients had combined posterior osteotomies and fusions Two patients required revision of the osteotomies in order to mobilise the deformities sufficiently for distraction to be effective

RESULTS - TUBERCULOUS KYPHOSIS (Table 2)

Of the 42 patients, 3 died as a result of surgery, [illegible] had the apparatus removed early and in one case, it was used as a holding device The remaining 36 patients were followed for an average of 2 9 years (range 1 25 to 4 5 years)

TABLE 2

TUBERCULOUS KYPHOSIS

Case number	Pre op degree (average)	Maximum correction		Follow up	
		Average	As a	Correction (average)	Length of time in years
1 to 10	117°	to 80° (Corr of 37°)	32	93° (Loss of 13°)	3 9
11 to 20	114°	to 70° (Corr of 44°)	39	77° (Loss of 7°)	3 1
21 to 27	106°	to 73° (Corr of 33°)	32	76° (Loss of 3°)	2 5
31 to 39	128°	to 101° (Corr of 27°)	22	104° (Loss of 3°)	1 7
Total number of patients 36	117°	to 81° (Corr of 36°)	31	88° (Loss of 7°)	2 9

There were no figures to indicate that deformities more proximal in the spine achieved better correction, because the variables were so great age activity of disease and previous surgery, etc From a mechanical point of view, however, it is apparent that the more prox mal regions in the spine have greater forces applied in the halo pelvic apparatus and the clinical impression is that the younger the patient the more active and the more recent and the more proximal the disease the greater the correction with the halo pelvic apparatus

The average pre operative angle of kyphosis was 117 degrees and after correction and fusion the average angle was 81 degrees representing a correction of 36 degrees (or 31 per cent) As most deformities were in the thoracic spine, where the normal kyphosis measures from 20 to 40 degrees (54), this correction is in fact better than it would seem from the angular measurements alone At

follow-up of the 36 patients, three years later, there was an average loss of 7 degrees of correction The final correction was 30 degrees (or 26 per cent)

Various factors were analysed to determine whether they had any significant influence on the final result and the correction achieved The younger patients who had active disease had a significantly better correction Those who had a more extensive mobilising excision of the internal kyphosis likewise had a better correction, as would be expected Surprisingly there was no difference between those patients who had had previous spinal fusions, and those who had no previous surgery

The patients (1) who had had previous fusions and (2) those without previous surgery were analysed separately Those with previous fusion (11 patients) had a pre-operative angle of 116 degrees corrected to 78 degrees (a correction of 38 degrees or 33 per cent) with a loss at follow-up of only 3 degrees

Those who had not had previous surgery (25 patients) had a pre-operative angle of kyphosis of 118 degrees corrected to 84 degrees (a correction of 34 degrees or 29 per cent) At follow-up a final correction of 89 degrees or a loss of 5 degrees was measured There was thus no marked difference in the end result whether the patient had had previous fusion or not

The patients were taken in four separate chronological groups (see Table 2), to evaluate whether significant improvement in either the techniques of surgical mobilisation or use of the halo-pelvic apparatus had occurred with increasing experience The average pre-operative angle of kyphosis was approximately the same and the degrees of correction were similar in the first three groups. However, the smaller correction in the fourth group (cases 31 to 39) reflected the greater deformity in those patients who have been treated latterly

Loss of correction after surgery

More than 10 degrees of loss occurred in 4 patients One expects to lose no more than 5 degrees if the basic rules are adhered to and if the bone grafts have been protected for a sufficient period of time loss of correction in several of the early patients was due to failure to carry out a routine posterior fusion The average loss of correction was 7 degrees

There was one pseudarthrosis in this group, probably caused by a posterior fusion too short to protect the vulnerable anterior grafts (case 18)

The average number of anterior spinal grafts used was 5 (usually rib struts), but in several of the patients with lumbar lesions, blocks of iliac crest were used The average length of the anterior spinal graft as measured on the first post-operative radiographs was five centimetres

Minimal loss of correction occurred under the following circumstances
1) where anterior and posterior fusions were done,
2) an adequate period of immobilisation in the halo-pelvic apparatus,
3) where a sufficient volume of autogenous bone graft was used,
4) when the posterior fusion extended proximally and distally well into the secondary lordotic curves (which were also corrected significantly with distraction),
5) when the sites of the posterior osteotomy were sufficiently covered with bone graft

The following case report is included to demonstrate the principles involved in correcting tuberculous kyphoses A fifteen year old male patient (case 20) had a kyphotic deformity of 121 degrees and clinical signs of spinal cord compression (Fig 14 a) The treatment programme included (1) excision of the entire internal kyphos to decompress the cord and mobilise the deformity, (2) gradual distraction (one to two millimetres per day) followed by (3) posterior osteotomies and a fusion Finally, rib grafts were placed under compression into the

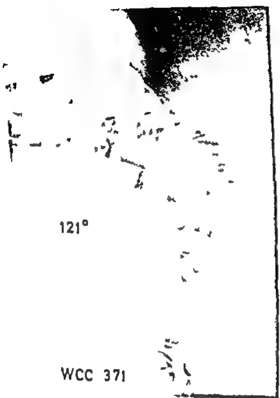

Figure 14 a Lateral radiograph before correction

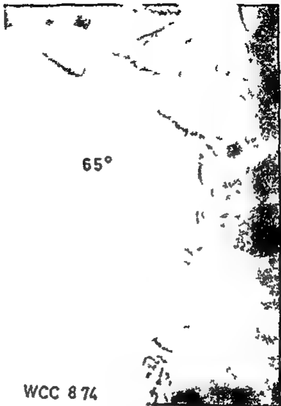

Figure 14 b Lateral radiograph three years and five months after surgery No loss of correction has occurred

Figure 14 a and (b) Case 20 *Tuberculous kyphosis in a fifteen year old male patient*

anterior interbody gap At follow-up three years and five months later the correction of 65 degrees had been maintained (Fig 14 b).

Neurological and cervical spine complications

16 patients had clinical evidence of marked spinal cord compression before surgery. 13 were completely relieved of their spasticity. 3 patients were paraplegic after surgery (cases 31, 34, 36), the pre-operative clinical condition indicated that they had penetration of the spinal cord by the tuberculous disease process (28), and this was confirmed at the time of posterior surgery in two of the patients where tuberculous follicles were detected on the dura mater

During the course of correction, 2 patients developed increased spasticity, with the combination of close observation and the ability to release the distraction immediately, the tension on the cord was reduced and the spasticity in both patients subsided

30 patients had cervical spine radiographs available 14 of these patients (47 per cent) developed cervical spine complications as a result of distraction in the halo-pelvic apparatus These and the neurological complications mentioned above will be discussed in full detail in the section on complications

SUMMARY AND CONCLUSIONS

42 patients with tuberculous kyphosis were treated by osteotomies, correction with the halo-pelvic apparatus and fusions

The average follow-up of these patients was [illegible] 9 years (range 1 25 to 4 5 years) The average initial correction of the kyphos was 36 degrees 3 patients died following surgery, all of them with severe deformities and respiratory insufficiency

3 patients with penetration of the cord by the disease process and near complete paraplegia were completely paraplegic after spine surgery

Late neglected kyphotic deformities have associated cord compression

and respiratory insufficiency They can only be corrected with any safety by multiple staged operations and with gradual distraction before fusions are done The halo-pelvic apparatus provides the stability necessary for this programme of management and does not interfere with the respiratory impairment from which these patients suffer

2 PARALYTIC SCOLIOSIS

Introduction

31 patients with paralytic scoliosis commenced treatment in the halo-pelvic apparatus There were 15 males (average age 13 ▮ years) and 16 females (average age 15 1 years)

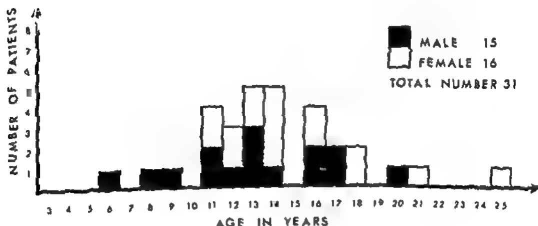

Figure 15 Paralytic scoliosis Barograph demonstrating the age and sex of patients

The average age of the patients was 14 1 years (see Fig 15) Three patients required removal of the apparatus before treatment had been completed (see Complications), four had had previous fusions which required osteotomy before correction, they will be discussed separately ('Salvage group)

The average period of time in the apparatus for the paralytic scoliosis patients was 7 6 months (Fig 16)

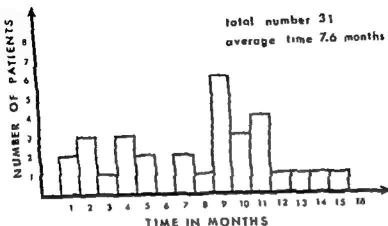

Figure 16 Paralytic scoliosis Barograph to show the time spent in the halo-pelvic apparatus The average time was 7 6 months

Site and extent of deformity

The curve types were as follows thoracic, 13 patients, thoraco-lumbar, 12 patients, lumbar, 6 patients The average major curve measured 111 degrees (range 59 to 164 degrees), the average flexibility with suspension was 25 per cent These measurements were made from radiographs taken with the patient suspended from a head halter, a posture maintained without discomfort for several seconds.

An average number of 9 vertebrae was involved in the major curve (range from 6 to 14 vertebrae) The barograph (Fig. 17) confirmed that the most common vertebrae involved were thoracic 10 and 11, with a high incidence of lumbar vertebrae in the major curve

Paralytic pelvic obliquity will be discussed separately, as it is felt that this deformity is major enough to warrant separate consideration

and respiratory insufficiency They can only be corrected with any safety by multiple staged operations and with gradual distraction before fusions are done The halo-pelvic apparatus provides the stability necessary for this programme of management and does not interfere with the respiratory impairment from which these patients suffer

2 PARALYTIC SCOLIOSIS

Introduction

31 patients with paralytic scoliosis commenced treatment in the halo-pelvic apparatus There were 15 males (average age 13 0 years) and 16 females (average age 15 1 years)

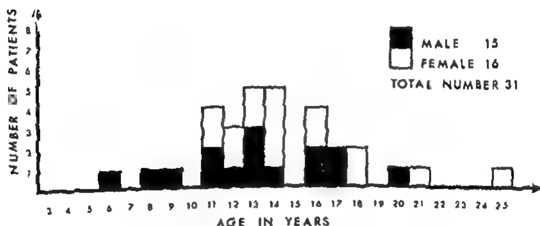

Figure 15 Paralytic scoliosis Barograph demonstrating the age and sex of patients

The average age of the patients was 14 1 years (see Fig 15) Three patients required removal of the apparatus before treatment had been completed (see Complications), four had had previous fusions which required osteotomy before correction, they will be discussed separately (Salvage group)

The average period of time in the apparatus for the paralytic scoliosis patients was 7 6 months (Fig 16)

Other surgery involved

Of the 31 patients with paralytic scoliosis only 8 did not require associated surgery for their limb deformities The majority required extensive surgery for correction of hip and knee contractures, the result of long standing poliomyelitis The general aim of the treatment was to make the patient as independent as possible, and to allow him to sit or walk with the minimum possible effort required

METHODS OF TREATMENT

The treatment programme (Table 3) included correction with the halo pelvic apparatus followed by

A) posterior fusion without a Harrington rod (11 patients),

B) posterior fusion with a Harrington rod (3 patients),

C) Dwyer s operation and the supplementary posterior fusion without a rod (5 patients),

D) Dwyer s operation and posterior fusion with rodding (3 patients),

E) posterior releases without fusion followed by Dwyer s operation (2 patients)

The 7 patients not accounted for in this treatment summary were as follows

a) three patients had early removal of the halo pelvic apparatus,

b) four patients who had osteotomy and correction of previous posterior fusion masses will be considered later together with a similar number of idiopathic cases in the so called Salvage group

The patients who had the halo pelvic apparatus removed prematurely had a combined staged anterior (Dwyer) and posterior correction and fusion (2 patients), except for one (aged six years) who has not yet had surgery

A preference for supplementary anterior surgery

With 51 per cent (average) correction of a paralytic scoliosis possible with the halo-pelvic apparatus (range 24 to 81 per cent)

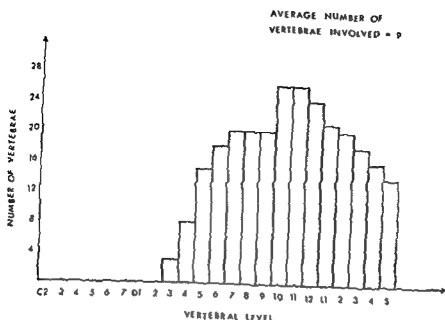

Figure 17 Barograph to demonstrate the vertebrae included in the major curve in paralytic scoliosis

Respiratory insufficiency

Although the association of paralytic spinal deformities with depleted lung function presents one of the major hazards in this field of work (23), this paper will not deal in any detail with the problem of respiratory insufficiency The accurate assessment of lung function before, during and after surgery is a vital aspect of the general management of these patients Supportive respiratory therapy before and during surgery, the need for tracheostomy, assisted respiration after surgery, the practicability of an anterior approach and the advisability of staging long spinal fusions are all questions which require to be evaluated in collaboration with a respiratory physician

Severe respiratory insufficiency was most commonly seen in patients whose curves were collapsing or situated in the thoracic spine Whilst post-operative respiratory function tests did not always indicate a great improvement in lung function, the patients were subjectively much better because they required less effort and energy with sitting or walking, once the spine had been centred and stabilised over the pelvis

and little further correction possible with the Harrington rod, the addition of the anterior approach seemed appropriate in many cases Further correction with Dwyer s instrumentation should be considered when the patient s type of scoliosis and his respiratory function deem it advisable A posterior fusion with rodding was then done to include the entire deformed spine (47) Further correction with Harrington s instrumentation was often neither possible because of osteoporosis nor was it advisable because of an already taut spinal cord

RESULTS

24 patients with paralytic scoliosis not previously treated had an average pre operative curve of 111 degrees corrected by the halo pelvic apparatus to 55 degrees, an average correction of 51 per cent

The average length of follow up was 3 3 years and the average loss of correction was 10 degrees

These patients have been grouped according to the type of surgery which they had undergone (Table 3) Group A (11 patients) had a posterior fusion without rodding Their average pre operative curve was 115 degrees which corrected to 57 degrees with distraction, a correction of 51 per cent Their average loss of 18 degrees at the follow up is a reflection of the failure to use internal fixation

Group B (3 patients) had posterior fusions with rodding following maximal correction with the halo pelvic apparatus Their curve averaged 100 degrees, and it corrected to 45 degrees with distraction, representing a correction of 55 per cent Their loss of correction at follow up was only 6 degrees, and the advantage of internal fixation is apparent when compared with Group A

Group C (5 patients) had Dwyer s instrumentation following distraction and subsequently a posterior fusion without rodding They had an average curve of 113 degrees corrected to 54 degrees with distraction an average of 51 per cent correction The Dwyer s operation achieved a total correction of [redacted] per cent, the loss of correction at follow up averaged only 1 degree

TABLE 3

PARALYTIC SCOLIOSIS - RESULTS

Group	Type of treatment	No of patients	Pre-operative degree	Correction with halo-pelvic apparatus (degrees)	(%)	Correction with Dwyer s instrumentation	Final correction at follow up (average 3 3 years)(degrees)
A	P S F without Harrington rod	11	115°	to 57°	51/	-	73° (Loss of 16°)
B	P S F with Harrington rod	3	100°	to 45°	55	-	51° (Loss of 6°)
C	Dwyer, P S F without Harrington rod	5	113°	to 54°	51	41° (64%)	42° (Loss of 1°)
D	Dwyer, P S F with Harrington rod	3	110°	to 56°	49%	31° (72%)	36° (Loss of 5°)
E	Dwyer with posterior osteotomies (no fusion)	2	112°	to 66°	41%	57° (49%)	74° (Loss of 17°)

patient and a Harrington rod was then inserted to protect the newly-added bone graft (case 64)

One patient, in whom a Harrington rod was not used, developed a pseudarthrosis eighteen months after immobilisation had been discontinued She subsequently had the pseudarthrosis repaired, and underwent a supplementary anterior fusion, because of the increasing kyphotic deformity which developed at the level of pseudarthrosis (case 51)

One patient, in whom a Harrington rod had not been used, had radiological evidence of a pseudarthrosis, but she declined further surgery The result was an increase in her lumbar curve which has now stabilised, the pseudarthrosis healed spontaneously and there has been no increase in the curve beyond the original pre operative deformity four years after surgery (case 47)

In summary, a pseudarthrosis was found in only one of the sixteen patients with paralytic scoliosis routinely explored, although only three of these patients had Harrington rods supporting the fusion masses, this would appear to be clinical confirmation of the inherent stability of the halo-pelvic apparatus

PEL IC OBLIQUITY

Eleven patients with paralytic scoliosis had pelvic obliquity (Table 4) The range of obliquity was from thirty to seventy degrees, an average of forty nine degrees The "angle of pelvic obliquity" was measured from an antero-posterior radiograph with the patient seated It is the angle subtended by the line drawn across the top of the first sacral vertebral body with the horizontal

Results

Pelvic obliquity was corrected from forty-nine degrees (average) to fourteen degrees (average), a correction of 72 per cent At follow up (average 3 3 years later), there had been an average loss of 5 degrees The final correction of pelvic obliquity was therefore sixty-two per cent Only two of the eleven patients had pelvic obliquity

Three patients in Group D (Dwyer's, posterior fusion and rod) with an average curve of 110 degrees corrected to 56 degrees with distraction (49 per cent correction) With Dwyer's operation this was increased to 72 per cent correction with an average loss of 5 degrees at follow-up

Two patients in Group E (posterior osteotomies, distraction and Dwyer's operation) with an initial average curve of 112 degrees had an initial correction of 41 per cent with distraction and a total correction of 49 per cent following Dwyer's instrumentation They lost correction because supplementary posterior fusions were not done The average loss of correction of 17 degrees at the time of follow-up demonstrates this point amply

Functional improvement

Seven patients had not been able to walk before surgery because of gross deformities and paralysis in their lower limbs, associated with severe collapsing scoliosis A further seven patients could walk with the aid of long braces and elbow crutches, but their walking required such an enormous effort that they preferred a wheelchair existence Of the seven patients who had no walking potential at all, two were made to walk by stabilisation of the spine and correction of the pelvic obliquity, together with multiple operations on the lower limbs The other five patients were far too extensively involved ever to walk, but as a result of surgery their sitting balance has improved to the point where they do not need their upper limbs for trunk support They are therefore free to sit in a suitable chair at a bench and employ themselves gainfully

Major loss of correction

Seven patients lost more than 10 degrees of correction at the time of follow-up Failure to use internal fixation was responsible for this loss in correction in five of these patients, the other two had Dwyer's operation without posterior fusions (cases 46, 50)

Exploration for pseudarthrosis

Sixteen patients had routine exploration of their posterior fusion masses at least six months after the fusion had been done Fifteen of them were judged to be solid A pseudarthrosis was repaired in one

patient and a Harrington rod was then inserted to protect the newly-added bone graft (case 64)

One patient, in whom a Harrington rod was not used, developed a pseudarthrosis eighteen months after immobilisation had been discontinued She subsequently had the pseudarthrosis repaired, and underwent a supplementary anterior fusion, because of the increasing kyphotic deformity which developed at the level of pseudarthrosis (case 51)

One patient, in whom a Harrington rod had not been used, had radiological evidence of a pseudarthrosis, but she declined further surgery The result was an increase in her lumbar curve which has now stabilised, the pseudarthrosis healed spontaneously and there has been no increase in the curve beyond the original pre-operative deformity four years after surgery (case 47)

In summary, a pseudarthrosis was found in only one of the sixteen patients with paralytic scoliosis routinely explored, although only three of these patients had Harrington rods supporting the fusion masses, this would appear to be clinical confirmation of the inherent stability of the halo-pelvic apparatus

PELVIC OBLIQUITY

Eleven patients with paralytic scoliosis had pelvic obliquity (Table 4) The range of obliquity was from thirty to seventy degrees, an average of forty-nine degrees The "angle of pelvic obliquity" was measured from an antero-posterior radiograph with the patient seated It is the angle subtended by the line drawn across the top of the first sacral vertebral body with the horizontal

Results

Pelvic obliquity was corrected from forty-nine degrees (average) to fourteen degrees (average), a correction of 72 per cent At follow-up (average 3 3 years later), there had been an average loss of 5 degrees The final correction of pelvic obliquity was therefore sixty-two per cent Only two of the eleven patients had pelvic obliquity

initially fully corrected by the apparatus (Table 4)(see Figs 36 a to d, page 106) Pelvic obliquity is a common accompaniment of paralytic scoliosis (11 out of 31 patients) It is seen with muscle imbalance above or below the pelvis (or both)

TABLE 4

PELVIC OBLIQUITY

No of patients	Case No	Pre-operative degree*	Post-traction degree	Correction maintained at follow-up (average 3 3 years)(degrees)
1	46	60	30	42

11	72	35	0	10
Average		49°	14° (72%) (correction of 35°)	19° (62%) (loss of 5°)

*See text for definition of The angle of pelvic obliquity (page 63)

When there is muscle imbalance above the pelvis, for example, with unilateral paralysis of the lateral trunk flexors, a progressive form of scoliosis with pelvic obliquity will develop which in its fully advanced form will lead ultimately to a dislocated hip (Figs 18 a and b)

Figure 18 a Case No 46 Severe collapsing scoliosis in a seventeen year old male patient Gross pelvic obliquity and dislocating left hip joint Note that the left iliac crest is almost horizontal and that the left hip joint is totally uncovered (arrow)

Figure 18 b Case No 46 Following gradual distraction, the scoliosis was reduced from 120° to 55° and the pelvic obliquity significantly but not totally corrected (arrow) Further correction of the pelvic obliquity and scoliosis can only be obtained with anterior surgery

Halo-pelvic distraction is a satisfactory method of reducing the scoliosis-pelvic obliquity complex when it is due to paralytic contracture For those patients with walking potential the fullest possible correction of obliquity is an essential aspect of their management A scoliosis fused with thirty degrees of residual spinal curvature will not be particularly significant but thirty degrees of residual pelvic obliquity will be disabling because of the extent to which the higher hip joint has been uncovered For patients with limited walking potential, covered hip joints are essential

The reason for this inability to correct pelvic obliquity totally with halo-pelvic distraction (only 2 out of 11 had total correction of the obliquity) is as follows whilst the soft tissues on the concavity of the scoliosis are shortening, there is increased compression on the concave aspects of the vertebral end plates reducing growth Less compression on the convex sides of the end plates of the vertebral bodies produces relatively more growth, the end result is that the vertebral bodies become wedge shaped Halo-pelvic distraction will overcome the soft tissue contracture but will not alter the shape of the vertebral bodies, this car only be refashioned by a direct approach, ideally by Dwyer s anterior instrumentation (Figs 19 a and b)

With preliminary traction followed by Dwyer s anterior instrumentation, the pelvic obliquity can in many cases be totally corrected When the scoliosis includes the fifth lumbar body, the anterior instrumentation should extend as far distally Extensive posterior fusion extending to the sacrum is then required to avoid a recurrence (38)

Should one consider using halo-pelvic distraction in pelvic obliquity, the altered anatomy of the iliac crests must be taken into consideration There is a definite risk of perforation of the intestines when inserting the pelvic pins in such patients The thoracic cage may often be intra-pelvic in the extreme types and the safest method, if the halo-pelvic apparatus is to be used, may be firstly to apply halo-femoral traction so that part of the obliquity can be overcome, before inserting the pelvic pins which can then be done with greater safety

F g re 19 a *Pre operative standing radiograph lote the dislocating right h ■ joint (arrow) associated with the pelvic obliquity*

F g e 19 b *Anter or poster or radiograph three years after corrective surgery (Dwyer s anterior sur ery distally to L5 and poster or sp ne fusion) lote the ri ht hip jo nt s now reasonably well covered (large arrow) The pelv c obliqu ty has been well corrected and fus on extends to the sacrum (small arrow)*

F ure 19 (a) and (b) Case 56 *Fourteen year old male patient with severe lu bar scoliosis and pelvic obl quity*

SUMMARY AND CONCLUSIONS

31 patients with paralytic scoliosis commenced treatment in the halo-pelvic apparatus. 24 completed treatment; the other 7 included:
1) 4 patients with previously fused spines; these will be discussed in the 'Salvage group". 2) 3 patients with pelvic obliquity had early removal of the halo-pelvic apparatus because of poor pelvic pin fixation. The average flexibility was 25 per cent in the suspension film (full body weight suspension); the average number of vertebrae in the major curve was 9. The average length of follow-up was 3 3 years.

As a correcting device, the halo-pelvic apparatus achieved an average correction of 51 per cent (range 24 to 81 per cent) for patients with an average paralytic scoliosis of 111 degrees.

The actual methods of fusion were posterior fusion without rodding, 11 patients, and with rodding, 3 patients Posterior fusion without rodding and with a supplementary Dwyer's operation, 5 patients, posterior fusion and rodding with Dwyer's operation, 3 patients, and Dwyer's operation with posterior osteotomies, 2 patients

The average loss of correction was 10 degrees The loss tended to be less in those patients with internal fixation and those where supplementary anterior surgery (Dwyer instrumentation) was employed

40 per cent of the patients with paralytic scoliosis whose cervical spine radiographs were reviewed showed evidence of degenerative changes; they will be discussed under Complications

11 patients in the series treated by the halo-pelvic apparatus had associated pelvic obliquity In only two was that obliquity totally corrected initially When pelvic obliquity is present and has not been sufficiently corrected, Dwyer's anterior instrumentation should be considered because of the importance of adequately covering both hip joints, particularly in patients with walking potential

The available evidence suggests that the halo-pelvic apparatus can be relied on to achieve an initial average correction of 51 per cent in paralytic scoliosis and 71 per cent of associated pelvic obliquity It has a significant part to play in those patients with poor

respiratory reserve

3 IDIOPATHIC SCOLIOSIS

Introduction

There were 15 patients with idiopathic scoliosis treated by the halo-pelvic apparatus 4 patients had had previous surgery (cases 75, 82, 86, 87, see appendix B) and they will be discussed separately in the Salvage group'

There was 1 male and 14 females and their average age at the time of surgery was 15 6 years The average time spent by these patients in the halo-pelvic apparatus was 6 4 months (range 1 to 12 months)(Fig 20) Their follow-up ranged from 1 5 years to 3 years (average 2 4 years)

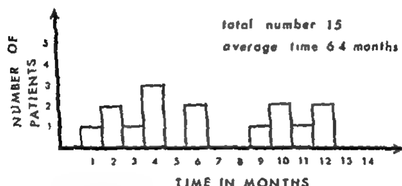

Figure 20 Idiopathic scoliosis Barograph demonstrating the time spent by the patients in the apparatus Average time was 6 4 months

The average curve before surgery, measured from pre operative standing radiographs, was 82 degrees (range 47 to 97 degrees) Barograph of the vertebrae included within the major curve (Fig 21) demonstrates that the vertebral levels T10 and T11 were the most frequently involved An average of seven vertebrae were included in each major curve

SUMMARY AND CONCLUSIONS

31 patients with paralytic scoliosis commenced treatment in the halo-pelvic apparatus 24 completed treatment, the other 7 included 1) 4 patients with previously fused spines, these will be discussed in the 'Salvage group' 2) 3 patients with pelvic obliquity had early removal of the halo-pelvic apparatus because of poor pelvic pin fixation The average flexibility was 25 per cent in the suspension film (full body weight suspension), the average number of vertebrae in the major curve was 9 The average length of follow-up was 3 3 years

As a correcting device, the halo-pelvic apparatus achieved an average correction of 51 per cent (range 24 to 81 per cent) for patients with an average paralytic scoliosis of 111 degrees

The actual methods of fusion were posterior fusion without rodding, 11 patients, and with rodding, 3 patients Posterior fusion without rodding and with a supplementary Dwyer s operation, 5 patients, posterior fusion and rodding with Dwyer's operation, 3 patients, and Dwyer's operation with posterior osteotomies, 2 patients

The average loss of correction was 10 degrees The loss tended to be less in those patients with internal fixation and those where supplementary anterior surgery (Dwyer instrumentation) was employed

40 per cent of the patients with paralytic scoliosis whose cervical spine radiographs were reviewed showed evidence of degenerative changes, they will be discussed under Complications

11 patients in the series treated by the halo pelvic apparatus had associated pelvic obliquity In only two was that obliquity totally corrected initially When pelvic obliquity is present and has not been sufficiently corrected, Dwyer s anterior instrumentation should be considered because of the importance of adequately covering both hip joints, particularly in patients with walking potential

The available evidence suggests that the halo-pelvic apparatus can be relied on to achieve an initial average correction of 51 per cent in paralytic scoliosis and 71 per cent of associated pelvic obliquity It has a significant part to play in those patients with poor

respiratory reserve.

3 IDIOPATHIC SCOLIOSIS

Introduction

There were 15 patients with idiopathic scoliosis treated by the halo-pelvic apparatus 4 patients had had previous surgery (cases 75, 82, 86, 87, see appendix B) and they will be discussed separately in the 'Salvage group"

There was 1 male and 14 females and their average age at the time of surgery was 15 6 years The average time spent by these patients in the halo-pelvic apparatus was 6 4 months (range 1 to 12 months)(Fig. 20) Their follow-up ranged from 1 5 years to 3 years (average 2 4 years)

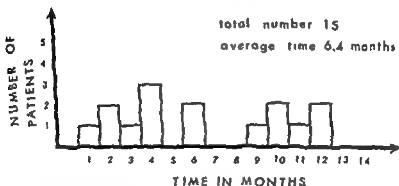

Figure 20 Idiopathic scoliosis Barograph demonstrating the time spent by the patients in the apparatus Average time was 6 4 months

The average curve before surgery, measured from pre-operative standing radiographs, was 82 degrees (range 47 to 97 degrees) Barograph of the vertebrae included within the major curve (Fig 21) demonstrates that the vertebral levels T10 and T11 were the most frequently involved An average of seven vertebrae were included in each major curve

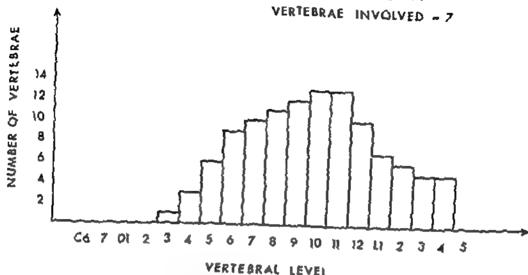

Figure 21. Barograph to demonstrate the vertebrae involved in the major curve in idiopathic scoliosis The average number of vertebrae involved was 7

The indication for the use of the apparatus in this series was, in most instances, a rigid deformity associated with a marked rotational component. The average age of the patients (15.6 years) suggests that the deformity had been present for some years and had developed significant vertebral body wedging which cannot be corrected by distraction

METHODS OF TREATMENT

Halo-pelvic distraction over an average period of nine weeks (range 3 to 10 weeks) was followed by a one-stage posterior fusion in seven patients, and a two-staged posterior fusion in one patient (case 74 with a double primary curve of 97 degrees) Harrington rods were used in five of the eight patients without further significant correction, the principle being to achieve the major correction before surgery Following distraction, three patients had Dwyer's anterior instrumentation without posterior fusion

RESULTS

The average curve after distraction measured 48 degrees, a correction of 42 per cent The best final corrections were obtained in the two patients (cases 78, 85, lumbar scoliosis) who had Dwyer's instrumentation performed after distraction Both corrected to zero The third patient with Dwyer's instrumentation had a thoracic scoliosis which lost nine degrees of correction after surgery

One patient (case 81), in whom the upper hook slipped out, lost 17 degrees of correction Two patients, in whom internal fixation was not used (cases 76, 77), lost 10 degrees of correction Case 77 actually lost correction whilst in the apparatus for a period of 10 months Loss of correction will be discussed under Complications (Part II, Chapter II)

Nine patients had cervical spine radiographs taken - four patients (44 per cent) developed cervical spine complications as the result of the halo-pelvic distraction, these will be discussed more fully in the section dealing with complications

SUMMARY : IDIOPATHIC SCOLIOSIS

Eleven patients with idiopathic scoliosis who had not had previous surgery had their curves corrected before fusion by the halo-pelvic apparatus Their average age was 15 6 years and the average major curve measured 82 degrees The average correction was 42 per cent and following this, eight patients had posterior surgery, with or without internal fixation, whilst three had Dwyer's anterior instrumentation performed

4 CONGENITAL KYPHOSCOLIOSIS

Clinical material

There were ten patients with congenital spinal deformities, four males and six females, one patient died with respiratory failure after surgery The average age at the time of surgery was 13 8 years

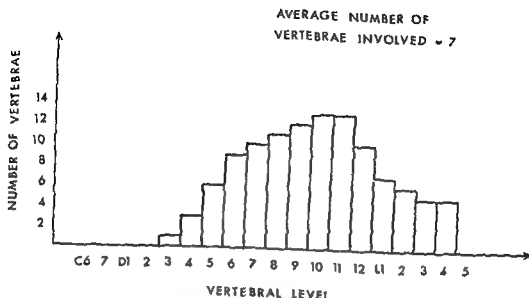

Figure 21 Barograph to demonstrate the vertebrae involved in the major curve in idiopathic scoliosis The average number of vertebrae involved was 7

The indication for the use of the apparatus in this series was, in most instances, a rigid deformity associated with a marked rotational component The average age of the patients (15.6 years) suggests that the deformity had been present for some years and had developed significant vertebral body wedging which cannot be corrected by distraction

METHODS OF TREATMENT

Halo-pelvic distraction over an average period of nine weeks (range 3 to 10 weeks) was followed by a one-stage posterior fusion in seven patients, and a two-staged posterior fusion in one patient (case 74 with a double primary curve of 97 degrees) Harrington rods were used in five of the eight patients without further significant correction, the principle being to achieve the major correction before surgery Following distraction, three patients had Dwyer s anterior instrumentation without posterior fusion

One patient developed a pseudarthrosis which required further surgery (case 97) This patient s curve deteriorated finally to its pre-operative level of deformity

5 NEUROFIBROMATOSIS

Clinical material

Six patients with neurofibromatosis were treated with the halo-pelvic apparatus, two males and four females Three of the six patients were paraplegic on admission, following previous surgery, they had been paraplegic for one week, three weeks and five months, respectively

The average length of time in the halo pelvic apparatus was 8 months (Fig 23), the average length of follow up was 3 years (range 2 to 4 years)

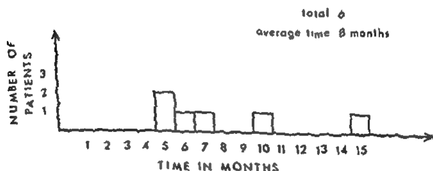

Figure 23 Neurofibromatosis length of time in halo-pelvic traction

The average number of vertebrae involved in the major curve was 8, the barograph demonstrates a peak of vertebral involvement at thoracic 9, 10 levels (Fig 24)

(range 10 to 19 years). Two patients were paraplegic on admission, one of them became paraplegic when correction of the deformity was attempted on a standard traction table in another centre. The average time in the halo-pelvic apparatus for these patients was 5.5 months (range 3 to 9 months) (Fig. 22).

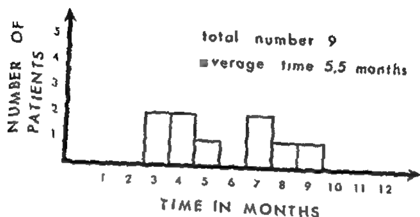

Figure 22 Congenital kyphoscoliosis Length of time in halo-pelvic distraction

The average degree of scoliosis measured was 98 degrees The halo-pelvic apparatus was used as a means of external spine fixation in two patients, to provide stability after surgery, so that in neither case was any correction attempted

METHODS OF TREATMENT

The two patients with congenital deformities and cord compression had decompression done Eight patients had mobilising osteotomies and five subsequently had staged anterior and posterior fusions following distraction Two patients had Harrington rods inserted and one had a Dwyer's instrumentation performed

RESULTS

The percentage correction in the congenital deformities was 26 per cent (range from 6 to 48 per cent)

One patient developed a pseudarthrosis which required further surgery (case 97) This patient's curve deteriorated finally to its pre-operative level of deformity

5 NEUROFIBROMATOSIS

Clinical material

Six patients with neurofibromatosis were treated with the halo-pelvic apparatus, two males and four females Three of the six patients were paraplegic on admission, following previous surgery, they had been paraplegic for one week, three weeks and five months, respectively

The average length of time in the halo pelvic apparatus was 8 months (Fig 23), the average length of follow up was 3 years (range 2 to 4 years)

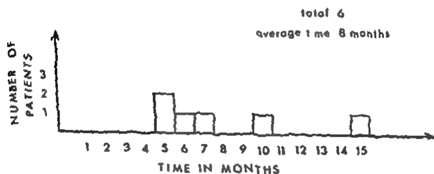

Figure 23 Neurofibromatosis Length of time in halo pelvic traction

The average number of vertebrae involved in the major curve was 8, the barograph demonstrates a peak of vertebral involvement at thoracic 9, 10 levels (Fig 24)

(range 10 to 19 years) Two patients were paraplegic on admission, one of them became paraplegic when correction of the deformity was attempted on a standard traction table in another centre The averag time in the halo-pelvic apparatus for these patients was 5 5 months (range 3 to 9 months) (Fig 22)

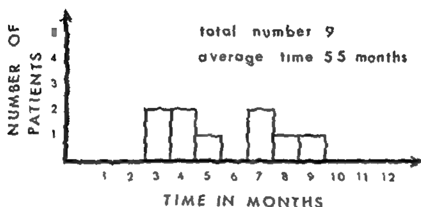

Figure 22 Congenital kyphoscoliosis : Length of time in halo-pelvic distraction

The average degree of scoliosis measured was 98 degrees The halo-pelvic apparatus was used as a means of external spine fixation in two patients, to provide stability after surgery, so that in neither case was any correction attempted

METHODS OF TREATMENT

The two patients with congenital deformities and cord compression had decompression done Eight patients had mobilising osteotomies and five subsequently had staged anterior and posterior fusions following distraction Two patients had Harrington rods inserted and one had a Dwyer's instrumentation performed

RESULTS

The percentage correction in the congenital deformities was 26 per cent (range from 6 to 48 per cent)

The loss of correction, even after anterior and posterior fusions, was significant Whilst initial corrections were good, the subsequent loss of correction left much to be desired, confirming the tendency of patients with this syndrome to deteriorate, in spite of staged anterior and posterior fusions Eighteen months after surgery, case 102 lost 50 degrees of correction with stress fractures through both anterior and posterior grafts which occurred despite radiologically sound fusions

SUMMARY AND CONCLUSIONS - CONGENITAL AND NEUROFIBROMATOSIS KYPHOSCOLIOSIS

Fifteen patients with congenital or neurofibromatosis spinal deformities completed treatment in the halo-pelvic apparatus One patient died after surgery because of respiratory failure Five of the fifteen patients (33 per cent) had cord compression or frank paraplegia at commencement of treatment Two of these patients had had previous extensive laminectomies performed The basic plan of treatment depended on the basic configuration of the spinal deformity and the presence or not of spinal cord compression Following decompression (when it was required) anterior and posterior fusions were used in the majority of patients In the congenital curves the average correction of the deformity was 26 per cent and in the neurofibromatosis patients the average correction was 43 per cent All had complete or near complete return of cord function and could walk six months after spinal surgery except for case 99 where complete para plegia had been present for five months before treatment (5 years later she had shown no further recovery)

Many of the associated conditions represented by this group of patients present ideal indications for the use of halo-pelvic apparatus, namely spinal cord compression, gross spinal curvatures, an unstable spine secondary to extensive laminectomies and the association of respiratory impairment

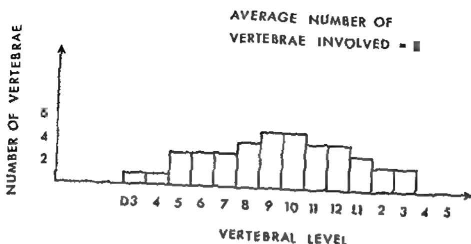

Figure 24 Neurofibromatosis Barograph to demonstrate the vertebrae involved in the major curve

METHOD OF TREATMENT

Of the six neurofibromatosis patients, the three who were paraplegic on admission had anterior decompression done, followed by anterior fusion (after distraction in two patients)

The three patients without cord decompression had staged anterior and posterior fusions following distraction (2 patients) and a posterior fusion following distraction (1 patient)

RESULTS

The average correction of patients with neurofibromatosis deformities was 43 per cent (range 6 to 85 per cent) Of the three patients who were paraplegic on admission, two recovered cord function and were able to walk 6 months after decompression and fusion The third patient (case 99) had been paraplegic for five months before surgery, by which time her cord function was irreversible

major values offered by the halo-pelvic apparatus in certain situations, particularly that of associated pelvic obliquity and respiratory insufficiency

SUMMARY AND CONCLUSIONS - SALVAGE GROUP

Eight patients with previous posterior fusions for scoliosis had the halo pelvic apparatus used in their treatment In two it was used for external skeletal fixation, and in six patients to correct deformities following osteotomies and prior to fusions Three patients had supplementary anterior fusions The average correction with the halo-pelvic apparatus was 40 per cent

6 SALVAGE GROUP

Eight patients with previous posterior spinal fusions for scoliosis were treated by the halo-pelvic apparatus

The average time in the apparatus was [redacted] 5 months The average pre-operative curve in this group was 88 degrees Two patients excluded from the average include case 73, who had initial correction following osteotomies with halo-femoral traction, and case 61, whose basic deformity was a kyphosis, which developed acutely at the site of a pseudarthrosis (paralytic scoliosis) The average follow-up was 2 5 years (range 1 5 to 4 7 years)

METHOD OF TREATMENT

Following fitting of the apparatus the previous fusion mass was explored and any metal present was removed Usually a Harrington rod, if it had been used, had fractured at the site of pseudarthrosis and had caused loss of correction Osteotomies were done at the apex of the curve and distraction was applied over the next few weeks

At re-operation the osteotomy sites were grafted and internal fixation with the Harrington rod was used (four patients) Three patients had supplementary anterior fusions performed (Table 5)

RESULTS

The average curve after correction was 52 degrees, a correction of 40 per cent An average of two spinal operations was performed per patient The one specific problem in using the halo pelvic apparatus in this group of salvage cases was that the pelvic pins precluded the use of graft from the posterior parts of the iliac crests It is in these patients, however, that large blocks of cancellous bone grafts are often required to plug the gaps created at the levels of the fusion mass osteotomies

This factor, however, may be of minor importance relative to the

CHAPTER II COMPLICATIONS

INTRODUCTION

The incidence of complications has been greatly reduced by the increased experience in the use of the halo-pelvic apparatus Improvements in the technique of fitting the apparatus and the introduction of force measurements, together with refinements in the clinical care of the patients have all contributed to a lower complication rate more recently

There are several complications however which inevitably occur with the use of the halo-pelvic apparatus such as osteoporosis, loosening of the pelvic pins and problems with distraction in the cervical spine

In the initial stages of experience with the halo-pelvic apparatus complications occurred which led to changes and refinements in the procedure All the complications encountered during the treatment of the first 104 patients with the halo-pelvic apparatus have been listed (Table 6, page 80) It is hoped that discussion of past mistakes will eliminate unnecessary complications The author believes that strict adherence to the detailed instructions itemised in Part I should prevent many of these complications from being repeated

COMPLICATIONS RELATED TO THE SKULL HALO

Infected halo pins

These occurred in 20 out of 104 patients and required replacement This is an easy matter with the modified halo in use, which has multiple threaded holes around its perimeter and allows a wide selection of alternative pin sites (Fig 2, page 17) In one patient an intense cellulitis developed in a pin site and, for fear of a cavernous sinus thrombosis developing, the halo and extension bars were removed until the infection had subsided

A chronic discharging sinus, following removal of the skull halo, occurred in 2 patients Radiographs revealed a small bony sequestrum,

which was removed by currettage, and the drainage subsided.

Slipping skull halo

In 8 patients the halo slipped off and both the halo and extension bars needed to be replaced under general anaesthesia The skull pins should be checked with the torque screw driver one week after fitting and tightened up if necessary Much bone resorption will often have occurred around the point of the skull pins due to pressure necrosis and they sometimes require several turns of the screw driver to return them to 5 5 pound inches (0 06 kpm) of torque force

Once the halo has begun to slip off it is difficult to replace, particularly if there is much tension in the extension bars It is a painful and frightening occurrence for the patient for which he requires adequate analgesic If only a couple of millimetres of slipping has occurred, then, with local anaesthetic infiltration, supplementary skull pins can be applied, providing that the skin around the existing skull pins is not excessively tented and ischaemic

Should the halo have slipped further than can be accepted, it is best removed together with the extension bars, to allow the patient to settle down It can then be reapplied several days later under local or general anaesthesia When a patient complains of looseness or slipping of the skull halo, it is important to act immediately or the halo will continue to slip rapidly, accelerated by the high forces being used The incidence of skull halos slipping has been greatly reduced by using six pins and by checking their tension one week after fitting These are now used routinely for heavier patients and patients requiring longer periods of treatment

COMPLICATIONS RELATED TO THE PELVIC PINS

Torn peritoneum

This occurred in one patient (case 71) who had a collapsing paralytic scoliosis (126 degrees) associated with pelvic obliquity of 60 degrees His clinical picture will be given in some detail because of the serious nature of the complication

TABLE 6

COMPLICATIONS DUE TO TREATMENT WITH THE HALO PELVIC APPARATUS

	Total number of patients (104)	Per cent

Slipping skull halo

In 8 patients the halo slipped off and both the halo and extension bars needed to be replaced under general anaesthesia The skull pins should be checked with the torque screw driver one week after fitting and tightened up if necessary Much bone resorption will often have occurred around the point of the skull pins due to pressure necrosis and they sometimes require several turns of the screw driver to return them to 5 5 pound inches (0 06 kpm) of torque force

Once the halo has begun to slip off it is difficult to replace, particularly if there is much tension in the extension bars It is a painful and frightening occurrence for the patient for which he requires adequate analgesic If only a couple of millimetres of slipping has occurred, then, with local anaesthetic infiltration, supplementary skull pins can be applied, providing that the skin around the existing skull pins is not excessively tented and ischaemic

Should the halo have slipped further than can be accepted, it is best removed together with the extension bars, to allow the patient to settle down It can then be reapplied several days later under local or general anaesthesia When a patient complains of looseness or slipping of the skull halo, it is important to act immediately or the halo will continue to slip rapidly, accelerated by the high forces being used The incidence of skull halos slipping has been greatly reduced by using six pins and by checking their tension one week after fitting These are now used routinely for heavier patients and patients requiring longer periods of treatment

COMPLICATIONS RELATED TO THE PELVIC PINS

Torn peritoneum

This occurred in one patient (case 71) who had a collapsing paralytic scoliosis (126 degrees) associated with pelvic obliquity of 60 degrees His clinical picture will be given in some detail because of the serious nature of the complication

The pelvic pin on the higher side of the pelvis could be palpated during its insertion both on the inside and the outside of the crest, indicating the thinness of the bone.

He vomited several times that evening and complained of abdominal pain. 24 hours later his temperature was 37.8°C and his pulse 100 per minute. He did not complain of much abdominal pain, but there was generalised abdominal tenderness; reflex abdominal guarding was not possible because of the extensive muscle paralysis A plain erect radiograph of the abdomen showed some gas beneath the diaphragm.

Bowel perforation was considered likely and an exploratory laparotomy was done immediately The pelvic hoop was removed but the two pins were left in position. A left paramedian incision was made and the findings were as follows: there was no bowel injury, both caecum and sigmoid colon were several centimetres from the pins. The right pin had torn a hole in the peritoneum measuring 2 by 2 centimetres, and approximately 30 millilitres of blood had trickled from that iliac crest through the rent in the peritoneum, producing the clinical signs of peritonitis. The left pelvic pin could be felt and seen from inside through the peritoneum It had produced a haematoma in the iliacus muscle The tear in the right iliac fossa peritoneum was repaired, the blood stained fluid was aspirated from the cavity and the abdominal wall closed in layers The pelvic hoop was then re-applied. Subsequently the patient had no further problems

After insertion of the pelvic pins, all patients must be observed closely for 24 hours, and should there be any fear of bowel perforation a general surgeon must be consulted immediately If a laparotomy is done, it is best to leave the pins in situ until the pathology is fully identified.

The intestinal surgery required will depend on the site and extent of the gut damaged as well as the delay in diagnosis Perforations of the small intestine, caecum or sigmoid colon, should be oversewn and the surrounding area drained If there has been extensive injury to the caecum or sigmoid colon, a right or left hemi-colectomy should be done; in the case of the sigmoid colon, a proximal transverse colostomy or caecostomy should be done in addition to the left hemi-colectomy (49).

There has been no instance of bowel injury in this series, although it has occurred on several occasions in other centres The danger with pelvic obliquity is apparent The anatomy of the bony pelvis is so grossly abnormal and the bone so poorly developed and osteoporotic that a large portion of the pin may be intrapelvic

Infected and loose pelvic pins

The pelvic pins commonly drained at some stage of treatment, this was usually a clear serous discharge, and cultures taken were often negative The skin around the pelvic pin occasionally grows up around the pin, and in many patients the pin sites remained dry for many months It is important, however, that they be examined and dressed each day, and cultures taken if the discharge becomes profuse or purulent, the patients activities should then be restricted and antibiotics considered Prophylactic antibiotic treatment should also be considered although it was not used routinely in this series

Patients with paraplegia and anaesthetic skin around the pelvic pins had a greater tendency to infection than those with normal skin sensation

There has been no osteomyelitis of the ilium but there have been several patients in whom a continuing discharge has become a problem In this respect, the possibility of cross infection must be remembered and, if the patient is being nursed in a large ward, he should be isolated

Methods of minimising the occurrence of infection include
1) applying the pelvic pins accurately, and with a minimum of trauma,
2) the anterior point of entry chosen, at or very near the tubercle of the crest, is subcutaneous and therefore has the least volume of soft tissue to rub against the pin If any point below this is chosen, the pin will penetrate the abductor muscle mass, and the constant rubbing of the pin against the muscle could produce continual discharge,
3) the thicker the pin, the less will be its excursion, and the less irritation it will produce in both bone and soft tissue The quality of the pin itself is important It must be high quality surgical stainless steel titanium is an ideal implant, but it is too

malleable for this purpose except for the lighter patients, 4) the constant friction of skin and subcutaneous fat against the pelvic pin can be minimised by a collodin dressing which reduces the movement of the skin around the pin The longer the pelvic pins are in position, the wider the tracks they create within the crests This is for several reasons a) there is constant sawing of the pin thread against the cancellous bone, b) immobilisation osteoporosis occurs above the pelvic pin, with resulting resorption of bony trabeculae In some instances, the windscreen wiper effect will be seen in radiographs after several months (Fig 25)

Two patients early in the series had loose pins replaced, but this is felt to be unwise, as the initial pin may have produced adhesions to the pelvic viscera, and the introduction of the second pin may expose the bowel to an increased risk of injury

Premature removal of the pelvic hoop

Five patients required early removal of the apparatus for the following reasons one patient had decided not to continue with his treatment, three patients had inadequate purchase of the pins in the pelvic bones (these patients all had severe degrees of pelvic obliquity associated with paralytic scoliosis) Another patient with pelvic obliquity had begun to sit up for the first time, and the anaesthetic skin over one ischial tuberosity had broken down and become infected, necessitating extensive plastic surgery before spinal surgery could be considered He, like the others, ultimately had a combined anterior and posterior correction and fusion

Ischial tuberosity pain

This occurred in five patients They had usually been in the apparatus for several months and complained of pain in the region of the tuberosity which was tender to palpate There may be no sign of infection either there or around the appropriate pelvic pin It is possible that the pin was irritating the sacro iliac joint with pain referral to the region of the tuberosity

Sensory nerve irritation

Three patients in the later stages of distraction developed pain in the anterior region of the thigh The femo[illegible]

within the pelvis lies in the groove between the iliacus and psoas muscles It is surprising how close the pin may be to the femoral nerve, if the mid part of its course is intrapelvic. One possibility is that inflammatory oedema, produced by the pin, irritates the cutaneous component of the nerve and produces pain

The other possibility is that the lumbar nerve roots are being over-stretched with production of sensory disturbances. Sunderland (59) has noted that when a mixed nerve is stretched there is never motor disability without sensory loss sometimes there may be altered sensation alone

Paraesthesia of the lateral cutaneous nerve of the thigh was observed in two patients In the first few patients in the series the pelvic pins were being inserted just lateral to the anterior superior spine, and presumably the lateral cutaneous nerve of the thigh, where it emerges just medial to the anterior superior iliac spine, was irritated at the point where it emerged from the pelvis, and produced paraesthesia This was of no consequence, and in both the affected patients it settled within several weeks

Hip contractures

The point of insertion of the pelvic pin is immediately above or at the upper fibres of origin of the tensor fasciae latae In paralytic patients who have been in the apparatus for several months this tissue will contract Alternatively, if the pin is intrapelvic in its mid portion and therefore related to the fibres of origin of the iliacus, a flexion contracture may be produced by contracture of the ilio psoas complex

On three occasions flexion abduction contractures required division when the halo-pelvic apparatus was removed Some patients favour moving about in a wheelchair during treatment, whilst this is acceptable, they must not be permitted to sit all day as severe contractures will develop Their hip joints should be placed through a full range of passive movement each day to prevent these contractures occurring (39)

malleable for this purpose except for the lighter patients, 4) the constant friction of skin and subcutaneous fat against the pelvic pin can be minimised by a collodin dressing which reduces the movement of the skin around the pin. The longer the pelvic pins are in position, the wider the tracks they create within the crests. This is for several reasons: a) there is constant sawing of the pin thread against the cancellous bone; b) immobilisation osteoporosis occurs above the pelvic pin, with resulting resorption of bony trabeculae In some instances, the "windscreen-wiper" effect will be seen in radiographs after several months (Fig. 25).

Two patients early in the series had loose pins replaced, but this is felt to be unwise, as the initial pin may have produced adhesions to the pelvic viscera, and the introduction of the second pin may expose the bowel to an increased risk of injury

Premature removal of the pelvic hoop

Five patients required early removal of the apparatus for the following reasons one patient had decided not to continue with his treatment, three patients had inadequate purchase of the pins in the pelvic bones (these patients all had severe degrees of pelvic obliquity associated with paralytic scoliosis) Another patient with pelvic obliquity had begun to sit up for the first time, and the anaesthetic skin over one ischial tuberosity had broken down and become infected, necessitating extensive plastic surgery before spinal surgery could be considered He, like the others, ultimately had a combined anterior and posterior correction and fusion

Ischial tuberosity pain

This occurred in five patients They had usually been in the apparatus for several months and complained of pain in the region of the tuberosity which was tender to palpate There may be no sign of infection either there or around the appropriate pelvic pin It is possible that the pin was irritating the sacro iliac joint with pain referral to the region of the tuberosity

Sensory nerve irritation

Three patients in the later stages of distraction developed pain in the anterior region of the thigh The femoral nerve in its course

disease process This phenomenon has been emphasised by Hodgson and co workers (28) and is clinically manifest by severe lower limb clonus and spasm

Discussion

The spinal cord begins at the lower end of the medulla oblongata and is described as extending normally to the intervertebral disc between the first and second lumbar bodies, although this is variable (29) In patients with long standing deformities, with congenital absence or infective destruction of the vertebral bodies, one cannot judge exactly where the spinal cord terminates The cord occupies the shortest course within the spinal canal, in scoliosis it will rest against the concavity and in kyphosis it will occupy an anterior position in the canal, abutting against the internal kyphos

The blood supply of the spinal cord has been a subject of increasing interest, the cord is nourished by three longitudinal vessels which extend from the origin of the cord to the conus medullaris they are two postero lateral arteries and a larger anterior spinal artery (29) This latter vessel receives contributions along its course which are not segmental, however, the most important member of these so-called feeder vessels is the artery of Adamkiewicz (1) which occurs on the left side in 80 per cent of patients and most frequently at about T10 vertebral level

Prompted by a high incidence of paraplegia following operations for severe scoliosis in adults, Dommisse (13) investigated the blood supply of the spinal cord and the dimensions of its canal He concluded that the blood supply is poorest and the spinal canal narrowest from the T4 to approximately the T9 vertebral level This region he named the critical vascular zone of the spinal cord"

Breig (2) has demonstrated that the spinal cord shortens and lengthens to accommodate relative changes in the length of the spinal canal He analysed the relative amounts of lengthening which occurred in different areas of the cord, the thoracic cord was least extensible (one centimetre), the lumbar cord intermediate (one to two centimetres) and the cervical cord most able to be deformed (1 8 to 2 8 centimetres) Three quarters of the physiological extension was provided

Broken pelvic pins

The pelvic pin may break either within the crest itself or externally between the skin and the pelvic hoop There have been two fractures of a pin adjacent to its attachment to the pelvic hoop and this has not presented particular difficulties If the pin breaks within the pelvis, then it must be replaced unless treatment is near completion when consideration may be given to removing the apparatus a little earlier than planned

SPINAL CORD AND NERVE INJURIES

Paraplegia

No patient sustained permanent paraplegia as a result of distraction Three patients had episodes of temporary spasticity and lower limb weakness during the course of treatment, one associated with coning of the brain stem into the foramen magnum The circumstances under which these temporary cord signs occurred were as follows

1 Case No 12 developed fever, papilloedema, headaches and hypertension following anterior and posterior osteotomies and distraction to correct a previously fused severe high dorsal tuberculous kyphosis A lumbar puncture excluded meningitis The symptoms settled when the distraction bars were shortened by 5 millimetres Some weeks later, he developed lower limb spasticity and this again was completely relieved by shortening the extension bars further

2 Case No 74 with a severe double-primary idiopathic scoliosis had some temporary motor loss in her lower limbs following posterior fusion In retrospect the tension left on the spine during surgery resulted in a taut spinal cord which was exposed to the risk of concussion

3 Case No 17 with severe tuberculous kyphosis and pre-operative partial paraplegia had a short, temporary episode of increased leg weakness following posterior osteotomy

Cases 31, 33, 34 - three patients with severe pre-operative spasticity were permanently paraplegic following surgery In no case was distraction an etiological factor All three had severe tuberculous kyphosis with penetration of the spinal cord by the tuberculous

In posterior surgery this will mean removing the two posterior bars and shortening the two anterior bars by 5 to 10 millimetres each, or removing all the bars The correction lost by releasing this tension will be negligible

Cranial nerve neurapraxias

Seven patients developed cranial nerve palsies during treatment the sixth cranial nerve in two patients, the tenth cranial nerve in four patients, and the twelfth cranial nerve in one patient All were temporary and recovered rapidly except for the twelfth nerve injury (case 91) which took one year before recovery was complete

Traction generated and transmitted during extension falls mainly on nerves pursuing vertical or obliquely vertical courses and this would explain the selection of nerves which sustain traction injuries with halo-pelvic distraction (58)

The abducent (VI) nerve runs upwards and is fixed where it leaves the ponto-medullary junction and where it crosses the apex of the petrous temporal bone The vagus (X) and hypoglossal (XII) cranial nerves run slightly upwards to leave the skull by way of the jugular and hypoglossal foramina, respectively Glosso-pharyngeal (IX) function is normally not tested but is closely assocaated with tenth and twelfth cranial nerves in the area of vulnerability at the base of the skull, it is presumably involved in many of these patients though its injury is more of anatomical than clinical significance

Brachial plexus lesions

Two patients sustained neurapraxias of the C5 6 nerve roots and one of the first thoracic nerve root These three temporary lesions occurred towards the end of distraction in patients with rigid deformities The fifth and sixth cervical spine nerves are more obliquely aligned in the neck and therefore more prone to injury by a vertically transmitted distraction force The first thoracic nerve crosses the neck of the first rib and presumably here it is tented and stretched by the distraction

The clinical significance of these nerve injuries is that no further correction can be achieved unless one mobilises the spine with

by unfolding of the cord and the remainder through the natural elasticity of the tissue.

The spinal cord is at risk with any form of rapid spine distraction because its axis is parallel to the longitudinal forces generated. With the cord under tension, Sunderland (58) noted mechanical failure occurring at values of 0.66 kp/mm^2 with a rate of extension of three inches per minute. Such a rate of extension in clinical circumstances could probably only be applied to the cord if the patient were forcibly corrected under general anaesthesia, whilst applying distraction with the extension bars

The lower thoracic cord would thus seem to be its most susceptible area and it is in this region that most spinal deformities have their peaks of incidence, as the barographs demonstrate (Appendix A). It is also, normally, a rigid region of the spine where antero-posterior and side to side motion permitted are approximately only 2 to 6 degrees at each segment (62)

Several factors must be remembered if paraplegia is to be avoided Pre-operative assessment should include myelography in order to exclude or to define an intraspinal lesion or to delineate the level and extent of cord compression, particularly in kyphoses and all congenital lesions There may well be myelographic evidence of a narrowed spinal cord without the obvious clinical signs of an upper motor neurone lesion, as for example with tuberculosis Should cord compression be detected it must be removed, to allow safe correction with gradual distraction

It is prudent to carry out a daily neurological assessment whilst carrying out distraction which must be gradual and well tolerated by the patient (Table 1, page 34) Regular lateral radiographs of the cervical spine and force measurements assist in determining a safe rate and tolerable extent of distraction

Patients with cord compression are in the greatest risk category, particularly if in the cases of tuberculosis, the disease has penetrated the spinal cord There is a high risk of paraplegia if one operates on a patient with a spinal cord under excessive tension, therefore the tension should be released at the time of operation

The duration of the paralysis varies from patient to patient, and bears no constant relationship to the cause or the apparent severity of the injury

COMPLICATIONS IN THE CERVICAL SPINE

77 patients in this series had radiographs of the cervical spine taken at some stage during treatment or at the time of the follow-up 45 patients had cervical spines which were regarded as radiologically normal, 32 patients had radiologically abnormal cervical spines These abnormal radiological findings included

1) Degenerative changes in the posterior joints of the cervical spine, the main features of which were diminution of the joint space, erosions and cystic lesions of bone adjacent to the joint Such latter changes were sometimes seen whilst the patient was still in the apparatus (26 patients)

2) Avascular necrosis of the proximal pole of the dens This was evidenced by cystic areas in the proximal end of the dens, by irregularity of the contour of the pole and adjacent sclerosis (13 patients)

3) Chronic atlanto axial subluxation This was confirmed by lateral flexion and extension radiographs of the cervical spine and was found in five patients at the time of follow-up

4) Avulsion of the ring apophysis of the inferior body of the second cervical vertebra occurred in one patient as a result of rapid distraction (Fig 26)

Of those with avascular necrosis of the dens (13 patients), ten had treatment for tuberculous kyphosis and one each for idiopathic, neurofibromatosis and paralytic scoliosis, respectively (60) Of these 13 patients with avascular necrosis of the dens, 7 had associated degenerative changes in the posterior joints

In a previous report (48) 65 per cent of the patients (44 out of 70) were observed to have developed changes in the cervical spine Loss of normal cervical lordosis was then considered abnormal In a later review of more radiographs many were found to have regained much of the normal lordosis and, when no other changes were apparent, and no clinical symptoms present, they were reclassified as normal

osteotomies and considers resuming traction thereafter. Even when this is done, the nerve injury is likely to recur when the same amount of distraction force is built up again, as occurred in the patient who sustained the hypoglossal nerve injury. This same observation has been made by DeWald (11). If these injuries are recognised very early and the extension bars shortened, then the prognosis for quick recovery is excellent.

The tensile strength of a nerve trunk depends essentially on its perineurium; tension in deforming nerve fibres will interfere with their blood supply. Studies in stress and strain have shown that the greatest elongation within the elastic limit is 20 per cent, except for some nerves where it may be as low as 6 per cent (59). The rate of application of deforming forces as well as their magnitude are instrumental in producing nerve lesions. When distraction is applied over a long period of time, nerves can be stretched well beyond the range of elasticity with little or no disturbance of function.

As the bundles elongate the nerve fibre deformation may produce arrest of circulation and obliteration of the vessels in the stretched nerve (59). Lundborg and Rydevik (32) demonstrated the effects of stretching the tibial nerve of the rabbit. The first vessels to be affected were the venules. There was arrest of venular flow with about 8 per cent elongation, at which stage there was the first intravasal evidence of tissue injury, granulocytosis, microthrombi and emboli.

Temporary nerve injuries involve interruption of conduction with preservation of anatomical continuity. These types of nerve injury have been termed first degree injuries by Sunderland (59) and neurapraxias by Seddon (56). In some cases conduction may be arrested on the verge of paralysis so that only a paresis results.

Most paralysed muscles will show recovery within six weeks. Sunderland (59) reported a series of patients with a duration of paralysis ranging from 17 to 60 days. Seddon (57) observed that mild distraction produces a lesion clinically indistinguishable from neurapraxia, the fibres are affected in order of their size, motor paralysis is complete, and sensory disturbance minimal. Recovery occurs rapidly and completely.

The duration of the paralysis varies from patient to patient, and bears no constant relationship to the cause or the apparent severity of the injury

COMPLICATIONS IN THE CERVICAL SPINE

77 patients in this series had radiographs of the cervical spine taken at some stage during treatment or at the time of the follow-up 45 patients had cervical spines which were regarded as radiologically normal, 32 patients had radiologically abnormal cervical spines These abnormal radiological findings included:

1) Degenerative changes in the posterior joints of the cervical spine, the main features of which were diminution of the joint space, erosions and cystic lesions of bone adjacent to the joint Such latter changes were sometimes seen whilst the patient was still in the apparatus (26 patients)

2) Avascular necrosis of the proximal pole of the dens This was evidenced by cystic areas in the proximal end of the dens, by irregularity of the contour of the pole and adjacent sclerosis (13 patients).

3) Chronic atlanto axial subluxation. This was confirmed by lateral flexion and extension radiographs of the cervical spine and was found in five patients at the time of follow-up

4) Avulsion of the ring apophysis of the inferior body of the second cervical vertebra occurred in one patient as a result of rapid distraction (Fig 26)

Of those with avascular necrosis of the dens (13 patients), ten had treatment for tuberculous kyphosis and one each for idiopathic, neurofibromatosis and paralytic scoliosis, respectively (60) Of these 13 patients with avascular necrosis of the dens, 7 had associated degenerative changes in the posterior joints

In a previous report (48) 65 per cent of the patients (44 out of 70) were observed to have developed changes in the cervical spine Loss of normal cervical lordosis was then considered abnormal. In a later review of more radiographs many were found to have regained much of the normal lordosis and, when no other changes were apparent, and no clinical symptoms present, they were reclassified as normal

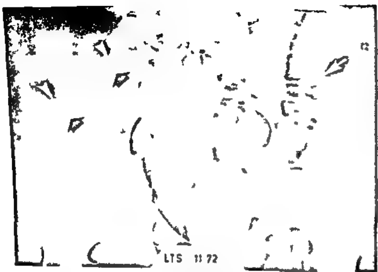

Figure 25 Case 98 Antero-posterior radiographs of pelvis after the pat ent had been in the apparatus for seven months Note 1) the widening of the pin tract within the iliac crest, the so-called windscreen wiper effect (arrows), 2) marked osteoporosis of the iliac crests above the p n tracts, 3) on the viewer s right side gas in the sigmoid colon overlying the left pelvic pin tract provides a good demonstration of the relationship of the sigmo d colon to the iliac crest (arrow)

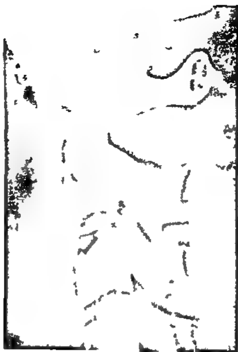

Figure 26 Case 16 Lateral radiograph of upper cervical spine to demonstrate avulsion of the ring apophysis of the inferior aspect of the second cervical vertebra due to rapid distraction

evertheless the incidence of radiological changes in the cervical spine is high

Four particular factors were analysed to determine their significance in relation to these above mentioned radiological cervical spine complications taken as a whole The factors analysed were a) the age of the patient, b) the period of time in the apparatus, c) the etiology of deformity, and d) the corrective forces used

.e age of the pati nt

Those patients with radiologically abnormal cervical spines were grouped mainly between 11 and 21 years 11 patients younger than 10 years had no radiological changes at time of follow up (range 2 to 5 years) (Fig 27)

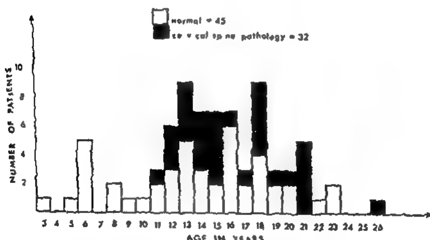

Figure 27 Barograph to demonstrate the age of patients with radiological changes in the cervical spine after treatment in the halo pelvic apparatus

There appeared to be a trend towards an increase in neck pathology correlating with the age of the patient (Fig 28)

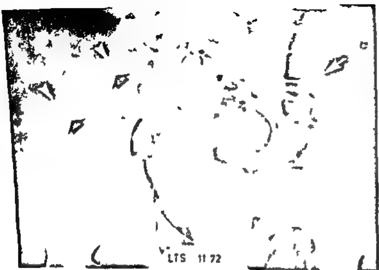

Figure 25 Case 98 Antero-posterior radiographs of pelvis after the patient had been in the apparatus for seven months Note 1) the widening of the pin tract within the iliac crest, the so-called windscreen wiper effect (arrows), 2) marked osteoporosis of the iliac crests above the p n tracts, 3) on the viewer's right side, gas in the sigmoid colon overlying the left pelvic pin tract provides a good demonstration of the relationship of the sigmoid colon to the iliac crest (arrow)

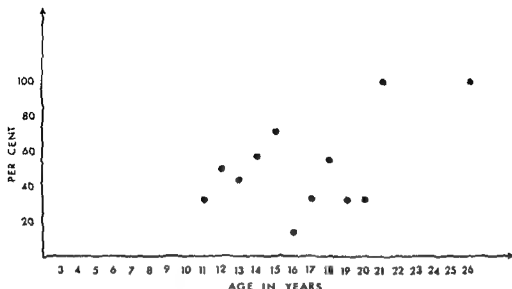

Figure 28 Plotted points to demonstrate the percentage of patients with abnormal cervical spines in the various age groups after treatment

Period of time in the apparatus

The longer the patients were in the halo-pelvic apparatus, the higher the observed incidence of radiological pathology in the cervical spine (Fig 29) In all groups of patients treated in the apparatus for longer than 7 months, a significant number developed cervical spine changes

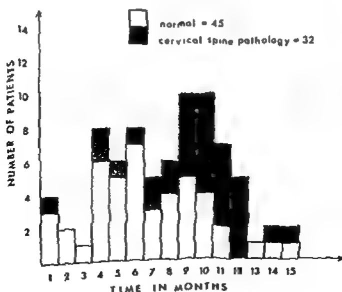

Figure 29 Barograph showing the relationship between radiologically abnormal cervical spines and the length of time in the halo-pelvic apparatus

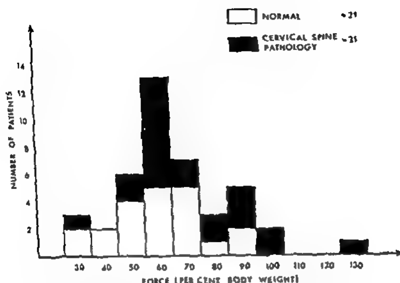

Figure 32 Barograph to demonstrate the relationship between radiologically abnormal cervical spines and the forces used in correction of the deformities

Neck pain is often experienced at some stage due to stretching If one examines the patient clinically whilst he has pain one can localise by palpation the segmental level at which the pain occurs The normal cervical lordosis disappears early and widening of the posterior synovial joints occurs more than in the intervertebral disc spaces which widen only slightly even with marked distraction Thus the neck not only loses its lordosis but becomes slightly kyphotic

It should be emphasised that absence of pain in the cervical spine during gradual distraction does not necessarily mean that all is well Very slow rates of distraction are compatible with freedom from neck pain Extensive damage to the cervical spine due to over-distraction can thus occur silently without either patient or surgeon being aware of it

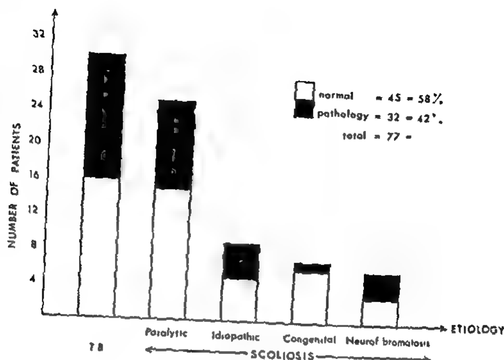

Figure 31 Barograph to demonstrate the incidence of radiologically abnormal cervical spines according to the etiology of the spinal deformity treated

Force measurements

Those who had force measurements and cervical spine radiographs available (42 patients) suggested that the higher the forces applied to the spine the greater the incidence of radiologically abnormal cervical spines The forces were recorded for this purpose as a percentage of the patient's body weight The critical level seemed to be 60 per cent of the patient's body weight, beyond which there was a higher incidence of neck pathology

Lengthening in the cervical spine with distraction occurs mostly at the upper two levels they are the most mobile, devoid as they are of protective intervertebral discs Case 71, a twelve year old male patient with a severe paralytic scoliosis, had lateral radiographs of the neck soon after treatment began and three months later (Figs 33 a and b). The amount of elongation which has occurred at the upper two levels with distraction is evident

The actual amount of cervical spine lengthening can only be judged with any accuracy from a lateral radiograph Clinically it is obvious that the neck has lengthened a good deal and the posterior arch of the axis, initially not easily palpable because of the overlying muscle mass, becomes readily felt through the stretched posterior soft tissues of the neck

There are numerous factors which determine how much the cervical spine itself will lengthen during spine distraction these include the patient s age, the strength and volume of his neck musculature, the rigidity of the spine deformity, the effectiveness of a mobilising osteotomy, if indicated, and the rate and extent of distraction

The combination of a rigid deformity with rapid distraction is likely to produce an acute injury, case 16 had a severe tuberculous kyphosis Following excision of the internal kyphos, distraction commenced at a rate faster than usual resulting in acute neck pain A lateral radiograph several days later demonstrated an anterior avulsion of the ring apophysis of the inferior aspect of the second cervical vertebra (Fig 26, page 92) He subsequently developed spontaneous fusion of the upper cervical units

Simultaneous correction of the deformity and lengthening of the cervical spine

Four unselected patients with tuberculous kyphosis had serial lateral radiographs of the correcting kyphos and the lengthening cervical spine compared (Table 7)

Fixed points were selected on the limbs of the kyphos of the pre operative films and of those at the completion of treatment These were compared with lateral cervical spine films before and at the end of distraction An estimate of the simultaneous amount of lengthening of the cervical spine could thus be made

There were differences in each patient the best ratio was case 27, for one centimetre of measured neck lengthening there was 6 4 centimetres of lengthening at the internal kyphos The "worst" ratio was case 23 for 2 centimetres of neck lengthening, 2 7 centimetres of lengthening at the internal kyphos was produced So many and varied

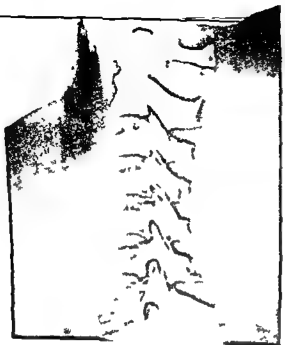

Figure 33 a Lateral *radiograph soon* after distraction commenced Note the distance between the dens and McGregor s line

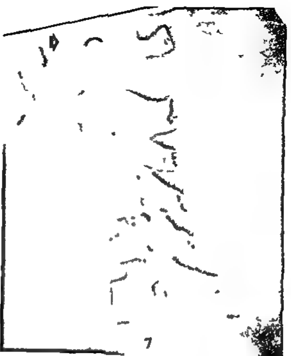

Figure 33 b *Three months* later, *there has been marked* distraction of the cervical spine, particularly at the upper two levels Note the increase in distance between McGregor s line and the top of the dens (arrow) Posterior joint spaces have widened more than the intervertebral disc spaces resulting in a slight kyphosis

Figures 33 *(a) and (b)* *Case No* 71 Lateral *radiograph of cervical* spine *after fitting of the halo-pelvic apparatus* and three months later after completion of distraction Patient had a severe collapsing scoliosis of 126° reduced to 63°

The actual amount of cervical spine lengthening can only be judged with any accuracy from a lateral radiograph Clinically it is obvious that the neck has lengthened a good deal and the posterior arch of the axis, initially not easily palpable because of the overlying muscle mass, becomes readily felt through the stretched posterior soft tissues of the neck

There are numerous factors which determine how much the cervical spine itself will lengthen during spine distraction these include the patient s age, the strength and volume of his neck musculature, the rigidity of the spine deformity, the effectiveness of a mobilising osteotomy, if indicated, and the rate and extent of distraction

The combination of a rigid deformity with rapid distraction is likely to produce an acute injury, case 16 had a severe tuberculous kyphosis Following excision of the internal kyphos, distraction commenced at a rate faster than usual resulting in acute neck pain A lateral radiograph several days later demonstrated an anterior avulsion of the ring apophysis of the inferior aspect of the second cervical vertebra (Fig 26, page 92) He subsequently developed spontaneous fusion of the upper cervical units

Simultaneous correction of the deformity and lengthening of the cervical spine

Four unselected patients with tuberculous kyphosis had serial lateral radiographs of the correcting kyphos and the lengthening cervical spine compared (Table 7)

Fixed points were selected on the limbs of the kyphos of the pre operative films and of those at the completion of treatment These were compared with lateral cervical spine films before and at the end of distraction An estimate of the simultaneous amount of lengthening of the cervical spine could thus be made

There were differences in each patient the best ratio was case 27, for one centimetre of measured neck lengthening there was 6 4 centi metres of lengthening at the internal kyphos The "worst" ratio was case 23 for 2 centimetres of neck lengthening, 2 7 centimetres of lengthening at the internal kyphos was produced So many and varied

are the factors involved that one can only rely finally on regular radiographs and clinical judgerents of the patient's reponse to treatment.

TABLE 7

23	2.7	2.0
27	6 4	1 0

Corresponding simultaneous lengthening at the internal kyphos and cervical spine, measured from lateral radiographs at the end of distraction.

Continuing lengthening without actual distraction

A significant lengthening of the cervical spine can often be measured in patients held in the apparatus who are no longer undergoing active distraction If one measures the length of the cervical spine from a radiograph after the last operation and before the removal of the apparatus this lengthening may be as much as 5 millimetres This is more likely when several months have elapsed between the last operation and the removal of the apparatus and in patients with paralytic neck muscles Although one is not actively lengthening the spine it is continually deforming (or "creeping") with the passage of time (6) A typical example of this phenomenon is case 18, a patient with a severe lumbar tuberculous kyphosis, who was corrected by staged procedures and then remained in the apparatus for a further 8 months On comparing identical lateral radiographs of the neck at the time of fusion and at the time of removal of the apparatus 8 months later, there had been an increase in length of 0 5 centimetres in the cervical spine (Figs. 34 a and b).

There are two separate mechanisms which singly or together produce the pathological changes in the cervical spine They are 1) deformity

Figure 34 a Taken at the completion of surgery

Continuing lengthening without actual distraction

A significant lengthening of the cervical spine can often be measured in patients held in the apparatus who are no longer undergoing active distraction If one measures the length of the cervical spine from a radiograph after the last operation and before the removal of the apparatus this lengthening may be as much as 5 millimetres This is more likely when several months have elapsed between the last operation and the removal of the apparatus and in patients with paralytic neck muscles Although one is not actively lengthening the spine it is continually deforming (or creeping) with the passage of time (6) A typical example of this phenomenon is case 18, a patient with a severe lumbar tuberculous kyphosis, who was corrected by staged procedures and then remained in the apparatus for a further 8 months On comparing identical lateral radiographs of the neck at the time of fusion and at the time of removal of the apparatus 8 months later, there had been an increase in length of 0 5 centimetres in the cervical spine (Figs 34 a and b)

There are two separate mechanisms which singly or together produce the pathological changes in the cervical spine They are 1) deformity

occurs here, the greatest residual disability will be due to loss of motion at these levels

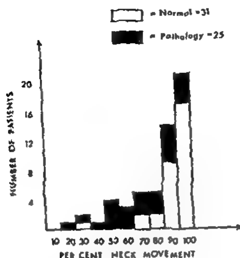

Figure 35 Barograph to demonstrate the relationship between radiologically abnormal cervical spines and clinical motion

INTESTINAL OBSTRUCTION

Three patients developed an acute duodenal obstruction of the type recently described by Evarts et al (21) They all had marked compensatory lumbar lordoses. As in nerve injuries, early diagnosis is important, since a delay in diagnosis affects the prognosis considerably

Occas onally small bowel obstruction may occur after the patient has had the extension bars fitted The constricting band can be removed from the compressed anterior duodenal wall by adjusting the extension bars thus reducing some of the lordosis

Diagnosis was promptly made when the patients started vomiting after the fitting of the extension ba s A plain erect antero posterior adiograph of the abdomen showed distension of the stomach and the first half of the duodenum To confirm the level of the obstruction, a small volume of soluble gastrografin was used, this is unnecessary in the established case as the gas shadows in the radiograph will

(distraction) both acute and chronic, and 2) prolonged immobilisation Acute over-distraction in association with a rigid curve is highly dangerous to the cervical spine (Fig. 26, page 92) but more especially to the integrity of the spinal cord and its blood supply. Chronic over-distraction accounts for the avascular necrosis of the dens (60). This is due to the proximal pole of that vertebra being pulled away from its blood supply. It was significantly more common in patients with marked lengthening of the neck (10 out of 13 patients with this lesion had tuberculous kyphosis).

A detailed account of the complication of avascular necrosis of the dens has been made recently (60) When the lateral radiograph of the cervical spine was examined with the patient in the halo-pelvic apparatus and the distance from McGregor's line to the top of the dens was greater than the vertical height of the posterior aspect of the third cervical vertebra, there was a high risk of avascular necrosis of the proximal pole of the dens occurring

Prolonged immobilisation together with persistent deformity of the posterior joints produces degenerative joint changes (20) Pannus grows into the joint across the articular cartilage causing interference with its nutrition and its early degeneration (55)

The available evidence suggests that (a) acute distraction, (b) excessive lengthening, and (c) prolonged immobilisation, singly or in combination, produce deleterious effects in the cervical spine

Clinical evaluation

Detailed measurements of neck motion were made in 56 unselected patients at least one year after treatment was complete. Nearly half (26 patients) had practically normal neck movements. Those with radiologically abnormal cervical spines had a significantly higher incidence of reduced motion (Fig 35) It has appeared that with time and use neck movements continue to improve for up to 12 months after treatment

The average patient, several years after treatment, had a painfree neck with loss of up to 30 degrees of rotation As most rotation occurs in the upper cervical units because the greatest distraction

Infection

Bone graft was taken from the iliac crest above the pelvic pins in many patients, in some of them the donor wound was slower in healing, but there was no significant problem. There was one posterior wound infection following the use of iliac crest bone but it settled with irrigation and drainage. If this bone is used, however, prophylactic antibiotics are necessary as the graft is potentially infected.

Continuing spinal growth in the apparatus

In the presence of an intact posterior fusion mass and continuing growth of the vertebral bodies, an increase in the deformity was observed in three patients despite being held in the apparatus. Case No. 52 was a nine year-old male patient with a collapsing paralytic scoliosis of 112 degrees (Fig. 36 a) which was corrected by halo-pelvic distraction to 21 degrees (Fig. 36 b). Although he was maintained in the apparatus for a further 12 months after surgery, the curve when the apparatus was removed measured 47 degrees, an exploration of the fusion mass six months after fusion having previously confirmed that it was solid (Figs. 36 c and d).

In the presence of marked rotational deformity, present in many of these patients, growth from the vertebral bodies would actually increase the length of the curve on the convex side whilst the concave or fused part of the spine is being bent by this continuing convex growth. The fusion mass is thus acting as if it were an unsegmented bar.

The other explanation in this situation is that because of the visco-elastic properties of tissues, gradual sagging of the fused spine and continuing lengthening of the cervical spine takes place even though no active distraction is taking place.

The practical points raised here are: 1) Internal fixation should be used with scoliotic deformities when possible. 2) The period of time in traction should be kept to a practical minimal period compatible with the patient's general physical state, particularly his respiratory function.

usually become conspicuous by their absence beyond the end part of the duodenum

OSTEOPOROSIS

Osteoporosis is an inevitable accompaniment of the immobilisation produced by the halo-pelvic apparatus (Fig 25, page 92) (4) Radiologically it is evident in all bony tissues between the skull and the pelvic pins Radiographs of the pelvis taken several months after completion of treatment with halo pelvic distraction confirm that bone lost above the pelvic pins has not been fully replaced

The clinical problems encountered with osteoporosis have been difficulties with internal fixation, notably seating the hooks for the Harrington rod, the vertebral body screws in Dwyer instrumentation and the pelvic pin fixation in paralytic patients

MISCELLANEOUS

Deaths

There were four deaths in the series Three patients died within five days of anterior spinal surgery, two within twenty-four hours of the operation One patient died within twenty-four hours of multiple posterior spinal osteotomies All had severe respiratory insufficiency and a moderate to severe degree of blood loss at the time of surgery The causes of death were paralytic ileus and pneumonia in one patient, acute respiratory failure and blood loss in one patient and acute respiratory failure in two patients

Pressure sore over the kyphos or rib hump

It is surprising how large an area of skin is made temporarily anaesthetic by the combination of posterior vertical and oblique skin incisions These patients with double skin incisions must be watched carefully, particularly if the back winder is being used This requires releasing every hour and the skin checked regularly for signs of redness or early breakdown

Infection

Bone graft was taken from the iliac crest above the pelvic pins in many patients, in some of them the donor wound was slower in healing, but there was no significant problem There was one posterior wound infection following the use of iliac crest bone but it settled with irrigation and drainage If this bone is used, however, prophylactic antibiotics are necessary as the graft is potentially infected

Cont ruing pinal gro-th in the apparat-s

In the presence of an intact posterior fusion mass and continuing growth of the vertebral bodies, an increase in the deformity was observed in three patients despite being held in the apparatus Case No 52 was a nine-year-old male patient with a collapsing paralytic scoliosis of 112 degrees (Fig 36 a) which was corrected by halo-pelvic distraction to 21 degrees (Fig 36 b) Although he was maintained in the apparatus for a further 12 months after surgery, the curve when the apparatus was removed measured 47 degrees, an exploration of the fusion mass six months after fusion having previously confirmed that it was solid (Figs 36 c and d)

In the presence of marked rotational deformity, present in many of these patients, growth from the vertebral bodies would actually increase the length of the curve on the convex side whilst the concave or fused part of the spine is being bent by this continuing convex growth The fusion mass is thus acting as if it were an unsegmented bar

The other explanation in this situation is that because of the visco-elastic properties of tissues, gradual sagging of the fused spine and continuing lengthening of the cervical spine takes place even though no active distraction is taking place

The practical points raised here are 1) Internal fixation should be used with scoliotic deformities when possible 2) The period of time in traction should be kept to a practical minimal period compatible with the patient s general physical state, particularly his respiratory function

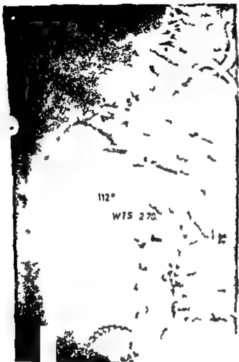

Figure 36 a Antero poster or radiograph with the pat ent seated Note extent of *pelvic* obliquity

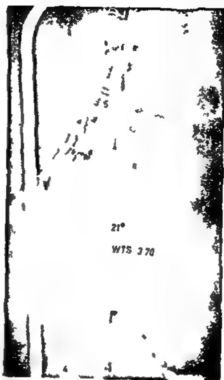

Figure 36 b Following gradual correction extensive *posterior spinal fusion was performed from* the first thoracic vertebra to the sacrum curve then measured 21°

Figures 36 a) (b) (c) and (d) Case 52 A *nine year old male patient with* severe collapsing paralytic scoliosis measur ng 112°, no walking potential because of severe four limb involvement

Figure 36 c Thirteen months later, curve has deteriorated to 47° despite being held during this period of time in the halo-pelvic apparatus The likeliest explanation for this phenomenon is continuing growth in the vertebral bodies (See text)

Figure 36 d Antero posterior radiograph of same patient four years after spinal fusion Further loss of correction in the fused spine, the curve now measures 60° Note the recurrence of the pelvic obliquity Internal fixation was not possible because of soft bone and the thinness of overlying soft tissues

Psychological disturbances

These were minimal and in fact non-existent when the method of treatment was explained fully to the parents and to the patient The recommended approach is to introduce a patient under treatment in the halo-pelvic apparatus to the parents and the patient and permit them to talk the matter over It is helpful to demonstrate the results before and after with radiographs and rarely will the parents of a child or the patient himself not consent to corrective surgery

One constant feature has been the dramatic improvement in the psychological attitude of the patient when he has seen the correction of his spinal deformity being obtained Supportive psychological therapy is an all important part of the overall technique with these patients and it requires the skill and gentle care of all physicians and paramedical personnel involved with the patient

DISCUSSION

When reviewing these results they must be assessed bearing in mind that 21 per cent of the patients had cord compression or frank paraplegia at the onset of treatment (tuberculous kyphosis 16 patients, congenital 2 and neurofibromatosis deformities 3 patients) In addition more than fifty per cent of all patients had significant respiratory impairment for which two required elective tracheostomy (tuberculous kyphosis)

Thus a large number of these patients had, in addition to severe spinal deformities, associated poor lung function and a compromised and severely threatened spinal cord

The actual average corrections achieved were tuberculous kyphosis 31 per cent, paralytic scoliosis 51 per cent, idiopathic scoliosis 42 per cent, congenital kyphoscoliosis 26 per cent, neurofibromatosis kyphoscoliosis 43 per cent and the salvage group (osteotomies of previous posterior fusion masses) 40 per cent

The correction of the tuberculous kyphosis series is better than it appears the average apex of the kyphos was at the ninth thoracic vertebra (Fig 11, page 45) and a natural kyphos of twenty to forty degrees exists in this region of the spine

The average correction of the patients with idiopathic scoliosis (42 per cent) was not as good as expected Significant derotation of the major curve does occur with the halo-pelvic apparatus when it is used in conjunction with the back winder (Fig 4, page 18) However, whilst the average curve was moderately severe (82 degrees) it would seem that the halo-pelvic apparatus in idiopathic scoliosis should be reserved for patients with rigid curves over 100 degrees, ideally with associated respiratory insufficiency making longitudinal traction in bed or on a frame unwise

The complications of greatest concern were pathological changes in the cervical spine mainly degenerative changes in the posterior joints, avascular necrosis of the dens and chronic atlanto-axial subluxation Most of the other problems encountered were temporary or avoidable, pelvic pin tract infection was common but was usually managed without difficulty There were no instances of osteomyelitis of the ilium nor of a case where the infection necessitated a change in the patient s management other than the three patients with pelvic obliquity who required early removal of the apparatus The problem and the difficulties and dangers with pelvic obliquity for the pelvic pins have been stressed The torn peritoneum in one patient has been emphasised in order to avoid its recurrence

The principle in using the halo-pelvic apparatus is to follow a planned technique to observe the patient closely, to organise a team approach for the patients management and to anticipate problems so that they are dealt with early and effectively

SUMMARY AND CONCLUSIONS

One hundred and four patients with severe spinal deformities commenced treatment in the halo-pelvic apparatus There were four post-operative deaths, the etiology of the spinal deformities was tuberculous kyphosis 42 patients, paralytic scoliosis 31 patients, idiopathic

scoliosis 15 patients, congenital kyphoscoliosis 10 patients, and neurofibromatosis kyphoscoliosis 6 patients The average time in the apparatus was 7 5 months

Eleven patients with paralytic scoliosis had associated pelvic obliquity Twenty-one per cent of patients had cord compression or frank paraplegia at the commencement of treatment Respiratory insufficiency was a common accompaniment of the spinal deformity especially in those patients with tuberculous kyphosis and paralytic scoliosis

The average corrections of the deformities were as follows tuberculous kyphosis 31 per cent, paralytic scoliosis 51 per cent, idiopathic scoliosis 42 per cent, congenital kyphoscoliosis 26 per cent, and neurofibromatosis kyphoscoliosis 43 per cent An analysis of a salvage group previously failed posterior fusions for scoliosis leading osteotomies, distraction and fusion revealed a correction of 40 per cent

Many complications due to distraction were easily remedied but the more serious were temporary spasticity in the lower limbs 3 per cent, temporary brachial plexus paresis 3 per cent, and cranial nerve palsies 7 per cent

Of seventy-seven patients who had cervical spine radiographs taken, thirty-two had radiologically abnormal cervical spines The most common neck complication was degenerative changes in the posterior synovial joints These appeared more commonly in the older patients, with excessive distraction and with prolonged time in distraction

The halo-pelvic apparatus is an effective instrument for the correction of severe deformities of the spine particularly for patients with poor respiratory function and cord compression or frank paraplegia Its use requires judgement and team work, close observation and attention to detail, in view of the complications encountered

INTRODUCTION

The aims of this project are (1) to analyse the stabilising effect of the halo-pelvic apparatus on the deformed spine and (2) to determine what proportion of the tension developed by halo-pelvic distraction is actually transmitted to the spine itself

Halo-pelvic distraction is becoming more widely known as a method for gradually correcting severe spinal deformities. Complications due to over-distraction have been reported, notably injuries to the cervical spine, paraplegia, and temporary nerve lesions (34, 48)

Considering these complications and the ignorance of the corrective forces being applied to the spine, a spring system on each of the four extension bars was developed in 1970 in conjunction with Clark and Kesterton of the Department of Mechanical Engineering at Hong Kong University (5) This gave a measure of the forces being used during treatment of the patients, the distraction forces were readily calculated from the extent of compression of the springs, but, there was no indication of what proportion of the measured forces was actually transmitted to the spine itself

In April 1971 Nachemson and Elfstrom reported their results of intravital wireless telemetry of forces in four patients with idiopathic scoliosis using a modified Harrington rod (41) The information obtained from this work permitted a more rational approach to the post operative management of the scoliosis patient (17, 18)

If this special Harrington rod was used in patients in conjunction with the halo-pelvic apparatus, the inherent stability of the latter could be assessed and the external forces, applied with lengthening of the extension bars and measured on the springs, could be checked against the internal measuring rod to give an assessment of the tension actually transmitted to the spine (Fig 37) This work was carried out at The Duchess of Kent Children's Orthopaedic Hospital, Hong Kong, in October-November, 1972 (19)

CLINICAL MATERIAL (Table 8)

There were four patients with severe paralytic scoliosis requiring preliminary traction before extensive spinal fusion with Harrington rodding Three of these were males and one female with ages ranging from 12 5 to 16 5 years Two of the patients' curves were thoraco-lumbar and two were thoracic in type, all four were convex to the right side The curves varied in extent from 95 to 145 degrees (average 112 degrees) The major curves involved from five to nine vertebrae, the angle of 'kyphosis ranged from 63 to 142 degrees

OUTLINE OF TREATMENT

The following steps were taken 1) fitting of the halo pelvic apparatus, 2) insertion of the special Harrington rod, 3) removal of the rod, standard posterior fusion and fitting of a standard Harrington rod, 4) removal of the halo pelvic apparatus, approximately six weeks later

Preliminary investigations were the routine tests prescribed for all patients with spinal deformities, and these included full radiographs and respiratory function tests

Details of treatment

1 The skull halo, pelvic pins and hoop were fitted in exactly the same manner as has been previously described (48) Fitting the extension bars several days later, with the patient seated and comfortably suspended by the skull halo, is easier, both for the surgeon and for the patient

2 The special Harrington rods were inserted by the method previously described (41) Normally at operation the two anterior bars are left in position on the apparatus, removing only the posterior bars to allow access to the spine In these patients all four bars were removed, so that the forces could be evaluated whilst the bars were being applied The operations were done with the patient prone on the Relton Hall frame (53)

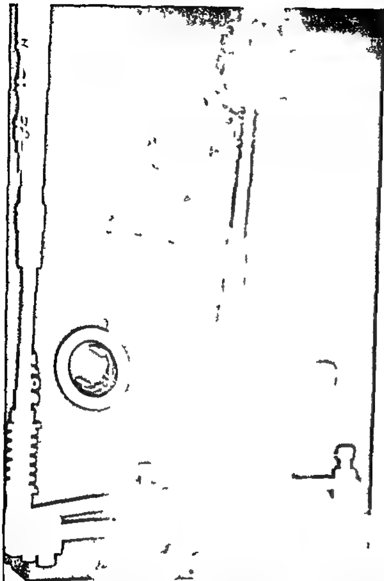

Figure 37 Patient No 1 Antero posterior radiograph of patient with paralytic scoliosis Note the extension bar of the halo pelvic apparatus with the compression spring at its base in addition to the telemetry rod with the coil and transmitter

A midline vertical posterior incision and the standard subperiosteal exposure of the concave bony elements was made The upper and lower Harrington hooks were inserted in the routine manner The special rod was then placed in position and the coil and transmitter put into an adjacent, subcutaneous pocket A force-gauging distractor (40) was used to distract the rod Initial readings were taken from the special rod at this stage and continued during the operation Over the next seven to ten days three sets of readings were taken at different times, (a) from the halo-pelvic springs, (b) from the special Harrington rod, and (c) from a spring balance suspending the halo with the extension bars removed

3 At re operation, approximately two weeks later, the telemetry rod was replaced with a standard Harrington rod and further distraction attempted The convex side of the curve was also dissected free of soft tissues and a routine posterior fusion done A two-stage correction was routine at the Department of Orthopaedic Surgery I in Goteborg (18) Supplementary anterior fusions were done in two patients (Nos 1 and 3) because of the kyphotic component in their deformities

4 The halo-pelvic apparatus was removed approximately six weeks after the spine fusion and full length body casts fitted to the patients

B At the end of operation
C Lifting the patient from the operation table to the bed

A During the operation (Table 9)

When the concave aspect of the scoliosis had been exposed and the upper and lower hooks placed in position, the modified Harrington rod was then connected up and the manual force gauging distractor used to extend the rod The distraction forces varied from 15 to 40 kp Patient No 2, in whom the 15 kp reading was made, had low readings throughout because of the osteoporotic bone which was unable to hold the upper hook Consequently, a firmer purchase for the seating of

the hook was obtained by using acrylic cement

The first readings taken from the telemetry rod ranged from 7 to 20 kp (column 3) In general terms, the force in the rod was approximately 50 per cent of those measured with the manual distractor However, in patient No 3, a gross 'kyphotic' element (142 degrees) produced a large element of friction between the rod and the hooks creating readings on the distractor which were higher than would otherwise have been anticipated

The differences in these two sets of readings (manual distractor and telemetry rod) might be due to the fact that the manual distractor measures total force of distraction including friction between hook and rod whereas the telemetry rod registers only the axial component of that force It will always therefore have a lower reading than the manual distractor

The forces in the special rod were again measured at the end of the operation By this time the stability of the two hooks had been checked and both the transmitter and the power transfer coil had been placed in pockets developed between the subcutaneous tissue and the dorso lumbar fascia The wound was closed in layers and continuous suction drainage was used Readings at this stage varied from 5 to 11 kp (Table 9, column 4), an average of 60 minutes having elapsed between the first and the second readings from the rods

The progressive decline of forces registered in the rod is evident, notably in patient No 4 where, over this 60 minute period, the rod readings fell from 18 to 7 kp The average initial reading for the Harrington rod was 14 5 kp and the average reading after 60 minutes at the end of the operation was 7 5 kp In broad terms, approximately 50 per cent of the force through the rod had vanished at the end of the operation, similar to the results previously reported (38, 41) There is an inevitable decline in forces due to the visco-elasticity of the stretched tissues, later readings will always be lower than the initial ones

TABLE 9

B. *End of operation - reapplying the extension bars* (*Table 9*)

The four extension bars were reapplied during which time readings of the internal force were taken. The anterior extension bars were reapplied first in patients No. 1 and No 4 and the posterior bars first in patients No. 2 and No. 3. The patient in each case was prone for the fitting of the first bars; in patient No. 1 the prone position was maintained but the other three patients were turned to the supine position on the table before the second set of bars was reattached to the halo and pelvic hoop. The length of the bars was not altered in any way from their pre-operative length.

During the refitting of the extension bars seven of the eight readings were less than those taken before the bars were attached. In patient No. 4 a significant reduction in the force on the rod (from 6 to 3 kp) was recorded with the fitting of the posterior bars in the supine position with the anterior bars already in place There are two explanations for this The refitting of the bars tends to unload the rod slightly and, with the progress of time, there is still further decline in the forces on the rod

C Lifting the patient from the operating table to the bed (Table 9)

The patient was lifted from the operating table and placed on his ward bed Patient No 1 needed to be turned to the supine position and then placed on the bed, the other patients were already supine on the operating table, the spinal frame having previously been removed Readings were taken whilst the patients were transferred from the table to their beds (except for patient No 4 where readings were not taken at this stage)

All three patients measured registered an increase in forces on the rod when compared with the last readings taken during the fitting of the second pair of extension bars (Table 9, columns 5 and 6) Patients No. 1 and No. 3 showed an increase of 3 kp force in the rod, patient No 2 an increase of 1 kp There was little influence on the rod in the patients during refitting of the extension bars, nor did there seem to be any consistent difference in the forces of the patients who had the anterior bars fitted before the posterior ones or those who had the bars fitted in a prone or supine position It is important, however, that this fitting be done carefully

*Cf patient L K , J Bone Joint Surg (A), 53A, 445-465, April, 1971

The stability of the apparatus is apparent when comparing this group of patients with a previous group who were not in the halo-pelvic apparatus (41) They had the telemetry rod applied and measurements were taken when the patients were lifted from the table to the bed

Table 10 shows two such groups, a non halo-pelvic and a halo-pelvic group In the non halo-pelvic group (Group A) the changes in the rod forces during lifting and turning varied from an increase of 4 to an increase of 14 kp, in three of these four patients the increase at this stage exceeded the highest forces registered during the operation itself, when the rod was first inserted With the stability of the halo-pelvic apparatus in the three patients where readings were taken (Group B), the maximum increase in the rod force during lifting and turning varied from 1 to 3 kp

D Readings in the rod after surgery and during the first three post-operative days (Table 11)

Day of operation

Coughing or straining during recovery from anaesthesia produced a mean increase of 2 kp in the rod (range 1 to 3 kp) One patient vomited during recovery (patient No 4) and an increase of 4 kp was recorded These figures are more meaningful when compared with the mean increase and range in forces measured with the special rod in the group of patients who were not in the halo pelvic apparatus (Table 11) This non halo-pelvic group had a mean increase of 5 kp (range 0 to 14 kp) during lifting and turning from the operating table to the bed

In the recovery phase after surgery, the non halo pelvic" group had a mean increase of 3 kp recorded in the rod (range 0 to 6 kp) In one patient (41) an increase of 30 kp was observed when vomiting occurred during the post-operative period

Comparing these two groups of patients, with and without the support of the halo pelvic apparatus demonstrates the stability and protection for the implanted rod provided by the halo pelvic apparatus The greatest difference was recorded in the two patients who vomited during recovery, the patient without external support had an increase of 30 kp recorded in the rod as opposed to the patient in the halo

pelvic apparatus in whom an increase of only 4 kp was measured

Day 2 to 3 post-operative

On the second or third day after surgery the patients used the Bird respirator for positive pressure breathing. In the halo-pelvic group mean increases of 1 kp were recorded (range 0 5 to 1.5 kp). When compared with group A (non halo-pelvic) there was little difference, for, in this group, the mean increase was the same (1 kp) and the range of increase similar (0 to 2 kp) It would seem that using the respirator places little stress on the spine.

On the third day after surgery the following activities were performed by the patients

1 Cycling exercises in bed
2 Arm exercises
3 Turning in bed to the convex side of the major curve
4 Turning in bed to the concave side of the major curve

1. Cycling exercises in bed

No increases were recorded in the halo-pelvic patients whereas in group A (non halo-pelvic) mean increases of 2 kp (range 0 to 5 kp) were recorded with this manoeuvre

2. Arm exercise

The patients were encouraged to lift weights with both hands and also to exercise against the resistance of a spring type chest expander In the halo-pelvic group no increase in forces was observed In the non halo-pelvic group mean increases of 7 kp were measured during the same exercise (range 5 to 10 kp)

The stability provided by the halo-pelvic apparatus is probably best demonstrated in this particular series of exercises, where no increase in forces on the rod were recorded

3 and 4. Turning in bed to the convex and concave sides of the major curve

The patients were assisted to turn in bed so that the convex part of

the instrumented curve was lowermost and readings were taken during this change in position There was a mean increase of 3 kp in the halo-pelvic group (range 1 to 7 kp)

They were then assisted back to the supine position and turned to the opposite side so that the concave side of the deformity was facing downwards The mean increase during this manoeuvre was zero (range 0 to 1 kp)

Similar increases were observed in both groups of patients, namely a larger increase in forces on the rod when the patient was turned to the convex side (Table 4)

E An assessment of the tension transmitted to the spine with the halo pelvic apparatus

Two separate investigations were carried out Firstly the springs at the base of the extension bars were measured with a vernier caliper in the routine manner and the forces calculated as described in Part I This was done with the patient seated All four extension bars were then lengthened by increments of 2 millimetres, and after each extension the springs were measured again and readings were taken from the special Harrington rod

The lengthening was done over approximately 20 to 30 minutes, and in each patient 8 to 10 millimetres of lengthening of the bars was tolerated without discomfort The external and internal force readings at various increases in spine length were taken and the respective points were plotted

Secondly, a spring balance, with cords and small hooks, was connected to the skull halo and upward traction through the halo was applied, approximately equal to that measured on the springs The four extension bars were then removed The force in the spring balance was then altered gradually in stages, and at each stage readings were taken from the spring balance and simultaneously from the internal rod These points were similarly plotted

DISCUSSION

As would be expected, there is a direct relationship within certain limits between the external force applied either by the spring balance or the halo-pelvic apparatus and the internal forces on the spine measured simultaneously on the special rod One should not draw definite conclusions from these curves because of the multitude of variables such as age, body weight and height, site of deformity, pattern of muscular imbalance, to mention only some of them The measuring systems do appear to be consistent, although the differences in each patient are vast

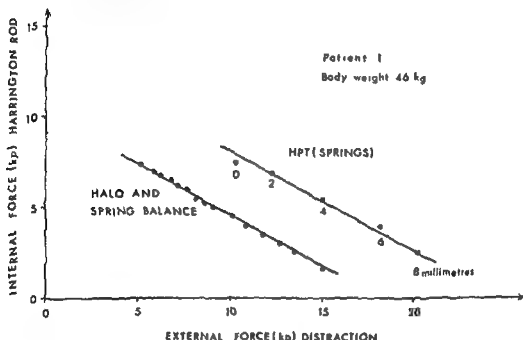

Figure 38 *Patient No 1 Plotted curves of internal force against* external force measurements The external force systems included
left curve the skull halo with the spring balance suspending it with the extension bars removed
right curve the springs compressed at the bases of the four extension bars

In patient No 1, with an internal force of 5 kp (Fig 38), the halo and spring balance registers 9 kp and the halo-pelvic springs 16 kp, a difference of 7 kp between the two external readings for the same internal measurement The difference can be explained by friction in the halo-pelvic spring measuring system and the error of the force readings of this system Furthermore, patient No 1 was a tall boy on whom long extension bars had to be used This creates difficul es in

the alignment of the four bars and there is a greater risk of friction in the system The spring balance applies its force directly on the halo, axially on the spine, and without either friction or bending moments

In patient No 4 (Fig 39) for the same internal reading (5 kp) the halo-pelvic springs register 6 kp and the spring balance springs 7 5 kp Note in this patient that the plotted curves have changed their position relative to one another the halo-pelvic spring curve has the lower offset In this patient, a small female, the bars were easy to align and no friction was noted The difference between the two curves can be explained by the error in spring measurements

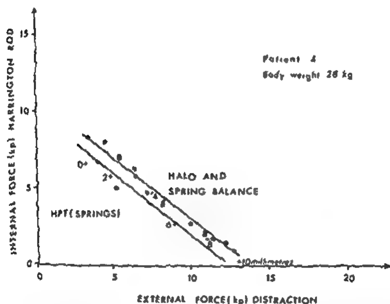

Figure 39 Patient No 4 Plotted curves of internal force against external force measurements The external force systems included
left curve the springs compressed at the bases of the four extension bars
right curve the skull halo with the spring balance suspending it with the extension bars removed

Perhaps the wider scatter of the points in patient No 4 (Fig 39), when compared with patient No 1 (Fig 38), is due to the fact that the external readings extend over a range from 3 to 12 5 kp In patient No 1, they vary from 5 to 20 kp It is likely that the

DISCUSSION

As would be expected, there is a direct relationship within certain limits between the external force applied either by the spring balance or the halo-pelvic apparatus and the internal forces on the spine measured simultaneously on the special rod One should not draw definite conclusions from these curves because of the multitude of variables such as age, body weight and height, site of deformity, pattern of muscular imbalance, to mention only some of them The measuring systems do appear to be consistent, although the differences in each patient are vast

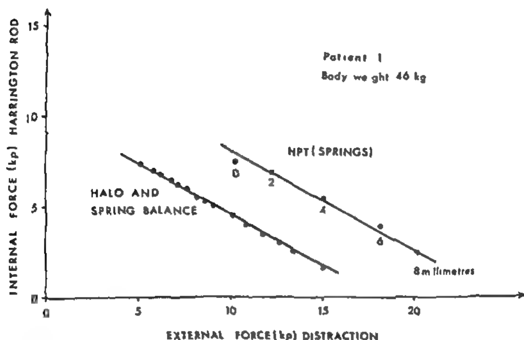

Figure 38 Patient No 1 Plotted curves of internal force against external force measurements The external force systems included
left curve the skull halo with the spring balance suspending it with the extension bars removed
right curve the springs compressed at the bases of the four extension bars

In patient No 1, with an internal force of 5 kp (Fig 38), the halo and spring balance registers 9 kp and the halo pelvic springs 16 kp, a difference of 7 kp between the two external readings for the same internal measurement The difference can be explained by friction in the halo-pelvic spring measuring system and the error of the force readings of this system Furthermore, patient No 1 was a tall boy on whom long extension bars had to be used This creates difficulti s in

the alignment of the four bars and there is a greater risk of friction in the system The spring balance applies its force directly on the halo, axially on the spine, and without either friction or bending moments

In patient No 4 (Fig 39) for the same internal reading (5 kp) the halo pelvic springs register 6 kp and the spring balance springs 7 5 kp Note in this patient that the plotted curves have changed their position relative to one another the halo-pelvic spring curve has the lower offset In this patient, a small female, the bars were easy to align and no friction was noted The difference between the two curves can be explained by the error in spring measurements

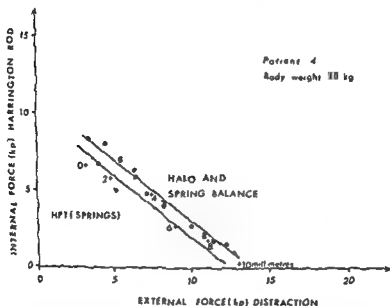

Figure 39 Patient No 4 Plotted curves of internal force against external force measurements The external force systems included
left curve the springs compressed at the bases of the four extension bars
right curve the skull halo with the spring balance suspending it with the extension bars removed

Perhaps the wider scatter of the points in patient No 4 (Fig 39), when compared with patient No 1 (Fig 38), is due to the fact that the external readings extend over a range from 3 to 12 5 kp In patient No 1, they vary from 5 to 20 kp It is likely that the

springs will tend to be more accurate once their initial slack has been taken up

For an increase in length of 8 millimetres for patient No 1 (Fig 38) the halo-pelvic springs registered an increase of 10 kp (from 10 to 20 kp) In patient No 4 (Fig 39) for the same increase in length, the external force increase was 7 8 kp (from 3 2 to 11 kp)

In the plotted curves the offsets are different in both patients for both external measuring systems when plotted against the force on the rod (The offset is found by extending the curves to where they meet the vertical axis, i e the external force is zero) In patient No 1, the offset is 10 kp for the halo and spring balance and 14 kp for the halo-pelvic springs For patient No 4, the offset for the halo-pelvic springs is 10 kp, and for the halo and spring balance it is 11 kp but again the slopes for each patient are the same

In patient No 1, the internal force is equal to 60 per cent of the externally applied distractive force In patient No 4, the internal force reduction was equal to 80 per cent In other words, for these two patients over this range of forces and under these specific circumstances, 60 and 80 per cent of change in the external force, respectively, appears as a change in the internal force The linear relationship between the force (stress) and deformation (strain) demonstrates the elastic properties of tissue (22)

In Fig 40 (halo-pelvic springs and internal readings) the curves for both patients are linear, the measured points fall nearly along straight lines and these lines fairly closely approximate equal slopes

In Fig 41 (halo and spring balance and internal readings) the curves are more or less linear and the two slopes are reasonably close to each other considering the differences between the patients ages, heights, body weights, and their site and extent of deformity

SUMMARY AND CONCLUSIONS

Four patients with severe paralytic scoliosis requiring preliminary pre-operative halo-pelvic traction had a specially designed telemetry rod inserted during treatment and over the next 10 to 14 days measurements were taken from the telemetry rods and from the compressed springs at the base of the extension bars as well as from a spring balance suspending the skull halo with the extension bars removed

Readings from the telemetry rod were taken from the time of its insertion at operation and an early decline in forces on the rod was observed Replacing the extension bars at the end of surgery did not have a significant effect on the forces on the spine measured from the rod Lifting the patient from the operating table and placing him on his ward bed, which was done without any particular precautions, produced a mean force increase of 2 kp in the rod

Coughing during recovery from anaesthesia produced a mean increase of 2 kp in the rod Vomiting (one patient) produced an increase of 4 kp and positive pressure breathing with a Bird respirator a mean increase of 1 kp in the rod

Cycling and arm exercises in bed three days after surgery produced no increase in rod measurements Turning the patient in bed to the convex side of the major curve produced a mean increase of 3 kp and to the concave side no increase was observed

With acute distraction (over 15 to 20 minutes), there was a linear relationship demonstrated between the externally applied force and the force simultaneously recorded on the telemetry rod in the spine This existed for both external systems - the halo-pelvic apparatus and the forces applied through the skull halo and spring balance with the extension bars removed

The direct relationship between stress and strain was demonstrated, illustrating elasticity as one of the mechanical properties of biological tissue

In the two patients who were assessed, 60 and 80 per cent, respectively, of changes in the externally applied force appeared as changes in the force measured in the spine itself by the telemetry rod

LS

When this clinical project commenced in 1969, studies were done both in the autopsy room and on cadaver specimens to determine the points of relative safety for inserting the pelvic pins. Complications related to skull and pelvic fixation have occurred (see Part II, Chapter II) the skull halo slipped and required replacing in eight patients, the apparatus was removed early in five patients because of insecure pin fixation There was tearing of the peritoneum in one patient Loosening of pins, with prolonged immobilisation, was commonly seen

This present study was therefore expanded to define more clearly the preferred anatomical landmarks and the mechanical aspects relative to the use of the halo-pelvic apparatus

The following subjects were explored

1) Fixation of the skull halo and the advantages, if any, of using supplementary skull pins
2) The anatomy of pelvic pin insertion with particular emphasis on defining safe landmarks
3) Basic mechanical studies of the bony ilium

I SKULL HALO FIXATION

An autopsy study was carried out to determine the forces required to dislodge a skull halo which had been applied by the standard clinical method (Part I) The ages of the four subjects ranged from 60 to 68 years and all had died of non-malignant diseases Each was firmly secured to the autopsy table and the skull halo applied with the pins inserted by a torque screw driver, which recorded five and one half pounds of torque force (0 06 kpm) The pins used were of the same dimensions as those used by the Rancho group (43)

A rope and pulley system was connected to the halo in such a way that the distraction force applied would be equally distributed amongst the four (or six) pins A spring balance, registering up to 200 kiloponds, was placed between the rope and pulley and a fixed point on the wall Traction forces were applied gradually for up to five

This present study was therefore expanded to define more clearly the preferred anatomical landmarks and the mechanical aspects relative to the use of the halo-pelvic apparatus

The following subjects were explored
1) Fixation of the skull halo and the advantages, if any, of using supplementary skull pins
2) The anatomy of pelvic pin insertion with particular emphasis on defining safe landmarks
3) Basic mechanical studies of the bony ilium

1 SKULL HALO FIXATION

An autopsy study was carried out to determine the forces required to dislodge a skull halo which had been applied by the standard clinical method (Part I) The ages of the four subjects ranged from 60 to 68 years and all had died of non malignant diseases Each was firmly secured to the autopsy table and the skull halo applied with the pins inserted by a torque screw driver, which recorded five and one half pounds of torque force (0 06 kgm) The pins used were of the same dimensions as those used by the Rancho group (43)

A rope and pulley system was connected to the halo in such a way that the distraction force applied would be equally distributed amongst the four (or six) pins A spring balance, registering up to 200 kilo-pords, was placed between the rope and pulley and a fixed point on ... 'on forces were applied gradually for up to five

minutes or until the halo slipped from the skull.

Four pins were used routinely; when the halo slipped from the skull it was reapplied in two subjects; new points of fixation, adjacent to those previously used, were chosen and two supplementary pins inserted two centimetres behind the posterior pins. The traction was then gradually reapplied

As for routine autopsy purposes, the upper part of the calvarium was then removed. The thickness of the region of the cranium where the pins had been inserted and the depth of the pits which lodged the pins in the outer table were measured

RESULTS (Table 12)

With four skull halo pins in place, a force equal to body weight or more was applied before the halo pins cut through bone and the halo slipped off In the first subject the halo could not be dislodged with a 200 kilopond force (three times the body weight) although the posterior pins had commenced to slip The anterior skull pins slipped first in the other three subjects

When two supplementary pins were added an additional 50 kiloponds of force was required to shift the halo in case 3, and in case 4 fixation could not be disturbed with 200 kiloponds of force

The depth of penetration of the skull pins varied from 0 3 millimetres to 1.2 millimetres with the same amount of torque force applied, it was most commonly 0 5 millimetres The deepest pin had lodged in the squamosal suture, which had not fused, and only the pin shouldering had prevented further penetration The average thickness of the skull at the points of pin insertion was 5 millimetres

DISCUSSION

Skull halo pins are usually inserted into the lateral aspects of the frontal bones and the posterior aspects of the temporal bones, regions which are safe because of the thickness of the skull.

In the temporal region, the frontal and temporal bones do not quite meet because of the interposition of the parietal and sphenoid bones This region of skull, termed the pterion, is 3 5 centimetres behind, and 1 5 centimetres above the lateral margin of the bony orbit (8) It lies deep to the temporal muscle and may be paper thin, on its deeper surface is the middle meningeal artery, which may produce a potentially lethal extra-dural haemorrhage if damaged Skull pins inserted in the temporal region may be hazardous The elected sites used clinically and in this present study, are preferable for reasons of safety, as the bone is so much thicker and denser

Perry (51) observed at post-mortem the pits made by the skull pins in the cranium of a patient with complete paralysis, who died after having a halo on for one month They had penetrated less than two millimetres Skull bones in children are less dense and presumably the pins would penetrate the outer table to a greater depth than observed in this study

Nickel and associates in 1968 (44) reporting on the use of the skull halo in 204 patients observed only 3 cases where the halo had slipped Many of the halos, however, had been fitted together with a body plaster and not a pelvic hoop It is likely that the forces applied through the skull halo with halo pelvic distraction are much greater than without the halo traction system This would explain the much higher incidence of skull halo slipping that we have had in our clinical experience with the halo-pelvic apparatus

Clinically the problem of the slipping skull halo has been met by 1) routine tightening of the skull pins one week after their fitting (to overcome loosening from pressure necrosis of the bone), and 2) the use of six pins when treatment is to be prolonged

2 THE ANATOMY OF PELVIC PIN INSERTION WITH PARTICULAR EMPHASIS ON DEFINING SAFE LANDMARKS

The standard clinical method of inserting the pelvic pins (47) was employed on 10 adult subjects at the time of routine autopsy Their ages varied from 40 to 70 years The instruments used included the drilling jig, the carpenter s brace and two diameters of pelvic pin

(6 35 and 8 millimetres) All the pins were inserted, with the aid of the jig, antero-posteriorly with the subject secured in the lateral position on the table The pins were inserted blindly on or near the iliac crest and their positions subsequently inspected relative to the soft tissues in the corresponding iliac fossa and in their relationship to the bone In several instances two or three pins were drilled into the crest on the same side but from different points of entry Twenty-four separate pins were inserted The bony pelvis appeared clinically normal and not misshapen in any of the subjects

RESULTS (Table 13)

The safest combination of entry and exit points was the tubercle of the crest and the posterior superior iliac spine (Fig 42, page 143) Commonly, these pins stayed intraosseous throughout their entire course, this depending to a large extent on the relative thickness of the bony iliac fossa at its centre In 5 out of 24 instances, the pin raised the inner cortical table of the iliac fossa, sometimes the middle portion of the pin was just within the fossa Here it was usually safe as the iliacus muscle forms the fossa bed When this situation arose the more flexible smaller pin was often deflected for up to 2 centimetres, by the curved posterior region of the iliac fossa and the adjacent sacro-iliac joint, before reengaging bone and penetrating the anterior sacro-iliac ligament Such pins finally emerged one or two centimetres more medial than anticipated The larger and more rigid pin steered a more direct course under these circumstances and was not deflected as far by the bony curve

Several pins were inserted inferior to the tubercle of the crest, through the tensor fasciae latae, and the outer table of cortical bone between the crest and the hip joint They were equally safe but at their point of entry they penetrate more soft tissue and are thus more likely to produce infection

In five cases (1R, 2L, 3R, 5R, 9L) the pin was medial to the iliacus, and in one of the subjects (2), it had wrapped the peritoneum around itself These five pins were all inserted near the anterior superior spine although one of them (2L) was inserted on the crest midway between the anterior spine and the tubercle of the crest In three

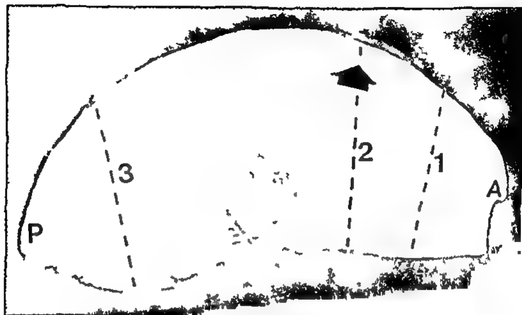

Figure 43 A lateral radiograph of an iliac crest removed at autopsy from a patient who died by accidental death Note the following points (A) the anterior and (P) the posterior superior iliac spine and the tubercle of the crest (arrow) Observe the thickness of the cortex at this point Also note the deficiency in the mid portion of the bone between two relatively thick anterior and posterior columns . Bone samples 1, 2 and 3 used in the study of strength of the iliac crest have been taken from areas designated 1, 2 and 3, respectively, in this specimen

cases (2R, 5L, 10R), the pin was seen external to the outer table over as much as 4 centimetres of its course *Provided the purchase in the strong anterior and posterior bony columns was adequate*, these were considered mechanically acceptable

DISCUSSION

The ideal pre requisites for pelvic pin insertion should be

1) They should be inserted safely without exposing the iliac crest, thus reducing the early incidence of infection
2) There should be no risk to the pelvic viscera
3) They should be inserted percutaneously, thus minimising the amount of soft tissue exposed to the pin
4) There should be good mechanical fixation, sufficient to withstand several months of treatment
5) The pins should be tolerated by the patient

The present investigation has obvious limitations, the main one being that patients requiring the halo-pelvic apparatus for treatment often have a poorly developed pelvis, commonly osteoporotic and occasionally oblique Secondly, this study has been done on a much older age group, nonetheless, guidelines emerge which might serve as an appropriate anatomical baseline

The crest of the ilium is cartilagenous at the time of birth With the process of ossification by the age of 9, it has been reduced to a cap of cartilage one centimetre in height (Fig 46, page 150) In this appear secondary centres of ossification at puberty (Fig 47, page 151), which fuse with the underlying bony crest by about twenty years (Fig 43) The iliac crest is then converted into a strong cortical cap particularly at the tubercle, which was demonstrated by the slab radiographs (Fig 44)

The bony ilium includes the upper part of the acetabulum and the flattened area above it Three parts of it are subcutaneous, the upper end, which is the crest itself, and the two projecting anterior and posterior spines The crest is convex upwards when viewed from the side, viewed from above it describes a sigmoid curve, the longer medial anterior component being the iliac fossa, and the smaller

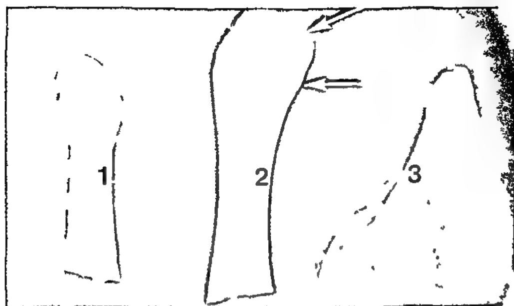

Figure 44 Slab radiographs of transverse sections of the iliac crest shown in Fig 43 and removed from the areas of the bone designated 1, 2 and 3, respectively

Section 1 is a transverse section midway between the anterior superior spine and the tubercle of the crest

Section 2 is at the level of the tubercle of the crest Note the well developed cortex at both the tubercle and forming the lateral table (arrows) Note that the iliac apophysis has completely fused to the iliac crest indicating full skeletal maturity

Section 3 is taken through the posterior part of the iliac crest, 3 centimetres anterior to the posterior superior iliac spine Note the medial part of the specimen includes a section through the sacro-iliac joint Note particularly the absence of strong cortical bone in this specimen

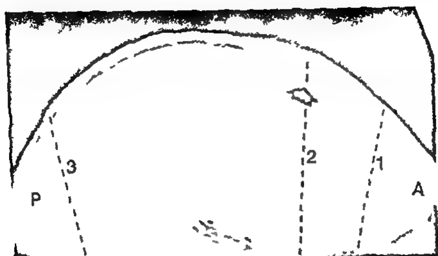

Figure 45 A lateral radiograph of an iliac crest removed at autopsy from a seventeen year old male who died by accident The anterior and posterior superior iliac spines are marked A and P respectively The tubercle of the crest is the thickest part of the crest (arrow Note that the iliac apophysis has not yet fused with the underlying crest Note also the strong anterior and posterior columns of bone within the crests separating a large deficiency of bone in the middle of the iliac fossa

Section 3 is taken through the posterior part of the iliac crest, 3 centimetres anterior to the posterior superior iliac spine Note the medial part of the specimen includes a section through the sacro-iliac joint Note particularly the absence of strong cortical bone in this specimen

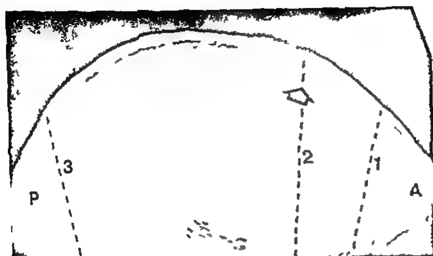

Figure 46 A lateral radiograph of an iliac crest re oved at autopsy from a seventeen year old male who died by accident The anterior and poster or superior iliac spines are marked A and P respectively The tubercle of the crest is the thickest part of the crest (arrow) Note that the iliac apo hys s has not yet fused with the underlying crest Note also the strong anterior and poster or columns of bone within the crests separating a large deficiency of bone n the middle of the iliac fossa

posterior laterally directed curve being the gluteal surface Even in young children, the anterior column of bone in the crest between the tubercle and the acetabulum can comprise a reasonable thickness of bone (7)

The ilium has a well developed anterior and posterior pillar of bone separated by a thin area where the cortical surfaces may be almost in contact Cunningham (8) states that the centre of the iliac fossa may even be defective The radiograph of the ilium removed at autopsy from a 17 year old patient demonstrates this deficiency in the middle of the bone (Fig 45, page 147) The iliac apophysis in this subject has completely ossified around the crest but has not yet united to it, it is thickest at the tubercle of the crest

There is thus not always the possibility of having the pelvic pin in contact with bone throughout its course, even when inserted as suggested, it may be inside or outside the ilium at its midpoint because of this thinness in the middle of the ilium It is therefore preferable that the pin penetrates a reasonable thickness of cortical bone, as it may be unsupported at its midpoint and therefore provides mechanically, relatively poor fixation

The iliac fossa gives origin to the iliacus muscle from the upper two thirds of its surface (8) This muscle is flat and triangular and fills the fossa It is covered by a fascial sheath, medial to which is the extraperitoneal fat, separating sheath from peritoneum On the right side is the caecum and on the left side the iliac part of the descending colon At the medial border of the iliacus is the psoas major and in the groove between the two lies the femoral nerve, branches of which supply the iliacus muscle (L2 and L3)

There is a reasonable degree of safety permitted, when inserting the pelvic pins, because of this cushion of iliacus muscle This cannot always be relied upon, it will be, occasionally, very thin, particularly in paralytic conditions affecting this muscle, and so every effort should be made to keep the pin within the bony ilium itself

Initially the forces exerted by the pelvic pins on the surrounding iliac bone during distraction are mainly vertical With time there is resorption of bone around the pins for two reasons 1) immobilisation osteoporosis and reduction of the natural compression forces reduce the number of cancellous trabeculae above the pins and there is a corresponding alteration of the surface area of bone in contact with the pin due to pressure necrosis, 2) the constant sawing effect of the pin thread wears away the surrounding bony trabeculae When the original track housing the pin has been enlarged, there will be an increase in the transverse forces and the pin will move to and fro widening the pin track even further

The aim of this study was to evaluate the holding strength of the tubercle relative to other points on the subcutaneous iliac crest An Alwetron machine (63) was used for this purpose At the same time, pins of varying diameters and threads were tested to ascertain their relative purchasing potential within the bone

The mechanical strength of the iliac crest in several regions was assessed Both crests in their entirety were removed from 7 patients who had died accidental deaths, their ages ranging from 16 to 30 years

A fixed length (2 centimetres) of the standard pelvic pin was inserted into the iliac crests at three different levels a) halfway between the anterior superior spine and the tubercle of the crest (sample 1), b) at the tubercle of the crest itself (sample 2), c) several centimetres anterior to the posterior superior spine sample 3) Fig 44, page 146) Blocks of bone encasing the pins were then excised from the crests

The length of pin was clamped in the Alwetron machine and the bone block firmly secured in a brass cylinder The pin was then distracted at a standard strain rate (one centimetre per minute) A continuous paper tracing provided a force-deformation curve and evidence when the pin had dislodged

posterior laterally directed curve being the gluteal surface. Even in young children, the anterior column of bone in the crest between the tubercle and the acetabulum can comprise a reasonable thickness of bone (7).

The ilium has a well developed anterior and posterior pillar of bone separated by a thin area where the cortical surfaces may be almost in contact Cunningham (8) states that the centre of the iliac fossa may even be defective. The radiograph of the ilium removed at autopsy from a 17 year old patient demonstrates this deficiency in the middle of the bone (Fig. 45, page 147). The iliac apophysis in this subject has completely ossified around the crest but has not yet united to it, it is thickest at the tubercle of the crest.

There is thus not always the possibility of having the pelvic pin in contact with bone throughout its course; even when inserted as suggested, it may be inside or outside the ilium at its midpoint because of this thinness in the middle of the ilium. It is therefore preferable that the pin penetrates a reasonable thickness of cortical bone, as it may be unsupported at its midpoint and therefore provides mechanically, relatively poor fixation

The iliac fossa gives origin to the iliacus muscle from the upper two thirds of its surface (8) This muscle is flat and triangular and fills the fossa It is covered by a fascial sheath, medial to which is the extraperitoneal fat, separating sheath from peritoneum On the right side is the caecum and on the left side the iliac part of the descending colon. At the medial border of the iliacus is the psoas major and in the groove between the two lies the femoral nerve, branches of which supply the iliacus muscle (L2 and L3)

There is a reasonable degree of safety permitted, when inserting the pelvic pins, because of this cushion of iliacus muscle This cannot always be relied upon, it will be, occasionally, very thin, particularly in paralytic conditions affecting this muscle, and so every effort should be made to keep the pin within the bony ilium itself

3 BASIC MECHANICAL STUDIES OF THE BONY ILIUM

Initially the forces exerted by the pelvic pins on the surrounding iliac bone during distraction are mainly vertical With time there is resorption of bone around the pins for two reasons 1) immobilisation osteoporosis and reduction of the natural compression forces reduce the number of cancellous trabeculae above the pins and there is a corresponding alteration of the surface area of bone in contact with the pin due to pressure necrosis, 2) the constant sawing effect of the pin thread wears away the surrounding bony trabeculae When the original track housing the pin has been enlarged, there will be an increase in the transverse forces and the pin will move to and fro widening the pin track even further

The aim of this study was to evaluate the holding strength of the tubercle relative to other points on the subcutaneous iliac crest An Alwetron machine (63) was used for this purpose At the same time, pins of varying diameters and threads were tested to ascertain their relative purchasing potential within the bone

The mechanical strength of the iliac crest in several regions was assessed Both crests in their entirety were removed from 7 patients who had died accidental deaths, their ages ranging from 16 to 30 years

A fixed length (2 centimetres) of the standard pelvic pin was inserted into the iliac crests at three different levels a) halfway between the anterior superior spine and the tubercle of the crest (sample 1), b) at the tubercle of the crest itself (sample 2), c) several centimetres anterior to the posterior superior spine (sample 3) (Fig 44, page 146 Blocks of bone encasing the pins were then excised from the crests

The length of pin was clamped in the Alwetron machine and the bone block firmly secured in a brass cylinder The pin was then distracted at a standard strain rate (one centimetre per minute) A continuous paper tracing provided a force deformation curve and evidence when the

Figure 47 Photo3rapl s of ve tical sections of iliac crest reroved at autopsy fror a seventeen year old female patient who d ed by accident Section 1 was cut from the anterior pa t of the liac crest and section 2 is the posterior pa t of the sa e crest Fote in section 1 the carti lagenous liac crest in which the ossific centre has appea ed Th s rep esents a slightly later sta3e of develop ent than that demonstrated in the previous ad og aphs Fig 46)

Figure 48 Photographs of a male adult s left iliac crest viewed from above The crest was removed at autopsy, placed in a bench vice and with a drilling jig, a standard sized pelvic pin was inserted through the crest The crest was then cut open, and the pin removed to demonstrate the thread created within the bone The arrow points to the anterior superior spine The pelvic pin was introduced at the tubercle of the crest (T) and it emerged at the posterior superior spine (P) Note particularly that the pin has stayed intraosseous throughout its course

RESULTS

The bone at the tubercle of the crest (sample 2) held the pin longer than either of the other two areas examined (Table 14, page 154) The anterior sample (sample 1) was intermediate in holding ability in five of the seven specimens, equal to the posterior sample in one (No 7) and weaker than it in one specimen (No 2)

The ultimate holding power of bone to any testing by this method depends on the volume of bone present, particularly cortical bone When the iliac apophysis has fused with the underlying crest at skeletal maturity, there is a strong ridge of cortical bone on the crest particularly at the tubercle (Fig 44)

The pins were extracted with the lowest forces in bone samples from the two adolescent subjects (cases 4 and 5) This is not surprising considering that the bony crests at this age have not yet fully ossified and still consist of a large proportion of cartilage (Fig 46)

Bench studies were done on four samples of iliac crests removed at routine autopsy They were fixed in a vice and pelvic pins inserted into them with a drilling jig The ilium was then cut down to the pin thread on one side and the bone was opened like a book (Fig 48, page 152) In each specimen tested the pin was intraosseous throughout its course The thread within the bone was firm to testing with a probe and had not been stripped by the drilling (the volume of bone replaced by the pin could be seen with a hand lens packed into adjacent cancellous trabeculae)

Pre drilling a sample of bone crest was next evaluated This is a standard engineering procedure where the hole is tapped first before the pin is inserted This method was assessed three times It produced excessive heat, with the bone actually smoking from the thermal insult When the drill went outside the bone in its course, the fine teeth from its end when it attempted to reengage the cortical

Legend

Site of sample	1	Iliac crest	half way between anterior superior spine and tubercle of crest
	2		midpoint on tubercle of crest
	3		crest 3 cm anterior to the posterior superior spine

In the skeletally mature patient the top of the crest is a thick cap of cortex In the younger patient, while this cortical cap is still developing, there is always a well developed outer cortical layer of the ilium which is best developed between the tubercle of the crest and the upper region of the acetabulum (Fig 46, page 150) This is firm enough for pelvic pin fixation, but it has one disadvantage in that it is not subcutaneous but covered by the muscular fibres of the tensor fasciae latae

White and Hirsch (63) demonstrated that the strongest bone of the iliac crest, when subjected to acute compression testing, was in the region of the tubercle of the crest The ultimate ability of bone to hold a threaded pin is a reflection of the volume of cortical bone present and at the tubercle it is thicker than at other regions of the crest Currey (9) noted that the density of cortical bone is about 2, whilst that of cancellous bone varies from 0 25 to 0 [redacted] (although the holding power of cortical bone is roughly thirty times stronger than that of cancellous bone)

2 Insertion of the pelvic pins is a safe procedure if a drilling jig and carpenter s brace are employed The recommended point of entry of the pin is on the tubercle of the crest or just inferior to this area, the exit point the posterior superior iliac spine If a pin is inserted near the anterior superior spine it is likely to be intrapelvic and therefore dangerous

3 With ossification of the cartilagenous iliac apophysis, a strong cap of cortical bone appears, covering the crest at skeletal maturity This is mechanically strongest in the region of the tubercle of the crest

GENERAL DISCUSSION AND SUMMARY

GENERAL DISCUSSION

The halo-pelvic apparatus is not a casual alternative method of treating spinal deformities, it is and should always be part of a carefully planned approach to the management of severe spinal curvatures It is a technique which demands discriminate selection of patients, precise observation and attention to nursing care

The patients selected should have severe curves, not sufficiently or efficiently corrected by any other methods in current use

The main indications for the use of the halo-pelvic apparatus in this series were tuberculous kyphosis and scoliosis following poliomyelitis If one or more of the following associated phenomena are present 1) anaesthetic skin, 2) respiratory insufficiency, 3) spinal cord compression, 4) a spine rendered unstable by tumour, multilevel laminectomies, etc , 4) pelvic obliquity (provided due care is taken with insertion of the pelvic pins) - then serious consideration should be given to using the halo-pelvic apparatus

Great attention has been focused on pelvic obliquity and the correction achieved with the halo-pelvic apparatus Only two of the eleven patients with pelvic obliquity had complete initial correction of the pelvic deformity It must be stressed again that these patients are in a high risk category because of the abnormal anatomy of the iliac crests and the subsequent possibility of perforation of intestines with pelvic pins When pelvic obliquity has been present for a long period there is such bony overgrowth on the convexity of the vertebral bodies of the scoliosis that adequate correction of the obliquity is not possible without anterior surgery

The importance of correcting the pelvic obliquity and thus providing adequate cover for the hip joint on the higher side will be fully appreciated If one chooses the right patient and plans and executes treatment with skill and judgement the halo-pelvic apparatus is uniquely effective

This is not to presume that there are no problems These have been dealt with in detail in Part II The complications must be weighed against the results which could not have been achieved by other

conventional methods of correction. Careful patient selection and the close observation recommended should ensure that the more serious complications do not occur. Likewise, pathological changes in the cervical spine will be minimised by restricting the use of the apparatus to those patients requiring it when there is no other satisfactory means of treatment available for obtaining an acceptable result.

Due consideration should be given to using the lowest corrective forces possible for the shortest period of time which is reasonable

The unique work in spinal instrumentation was commenced by Paul Harrington in 1948 It was many years later, however, before his method was fully accepted and now it is regarded as the treatment of choice for most forms of scoliosis It takes time and experience in many centres of the world to establish the reputation, indications and precise place for a new form of treatment

The available evidence suggests that the halo-pelvic apparatus is a *powerful* and effective method of correcting severe spinal deformities *Because* of the risk of pathological changes in the cervical spine its use should be restricted to those patients with deformities which cannot be effectively treated by the other methods in use today

SUMMARY

Part I

1) The history of the development of the halo-pelvic apparatus is discussed together with a general description of the apparatus The fitting of the apparatus is described in detail with emphasis laid on the accurate insertion of the pelvic pins, the use of the drilling jig and precise points of entry and exit in the iliac crest being the tubercle on the crest and the posterior superior iliac spine, respectively

2) During the post-operative period the four extension bars are placed connecting the patient's skull halo to the pelvic hoop For reasons of safety this is not done at the time of the fitting of the

3) Any patient with a spinal deformity severe enough to require treatment with the halo-pelvic apparatus should have pre-operative myelography and respiratory function studies done.

4) The four base lines which must be used to monitor the patients during distraction are a) regular clinical observation, b) daily neurological assessment, c) regular lateral radiography of the cervical spine, and d) the use of force measurements

5) When the halo pelvic apparatus is removed, a plaster body cast is applied until the bone graft has consolidated

Part II

6) One hundred and four patients with severe spinal deformities commenced treatment with the halo-pelvic apparatus The most common etiologies of the deformity treated were tuberculous kyphosis and paralytic scoliosis There were four deaths following surgery in the series The average time the patients spent in the apparatus was 7.5 months 21 per cent of the patients had cord compression or frank paraplegia at the onset of treatment

[illegible]he average correction of the deformity was as follows tuberculous kyphosis 31 per cent, paralytic scoliosis 57 per cent, idiopathic scoliosis 42 per cent, congenital kyphoscoliosis 26 per cent, [illegible] fibromatosis kyphoscoliosis 43 per cent These patients who [illegible] for previously failed posterior fusions had an [illegible] correction of 40 per cent

[illegible] common significant complication due to the use of the halo-pelvic apparatus was associated with distraction of cervical spine (77 [illegible] with radiographs of cervical spine were examined) Degenerative changes in the posterior joints of the cervical spine (34 per cent) and avascular necrosis of the upper pole of the dens (17 per cent) were the most common neck complications Some of the patients [illegible] changes in the axis also had posterior joint changes, therefore these percentages should be interpreted accordingly Cranial nerve [illegible] occurred in 7 per cent of the patients and brachial

conventional methods of correction Careful patient selection and the close observation recommended should ensure that the more serious complications do not occur Likewise, pathological changes in the cervical spine will be minimised by restricting the use of the apparatus to those patients requiring it when there is no other satisfactory means of treatment available for obtaining an acceptable result

Due consideration should be given to using the lowest corrective forces possible for the shortest period of time which is reasonable

The unique work in spinal instrumentation was commenced by Paul Harrington in 1948 It was many years later, however, before his method was fully accepted and now it is regarded as the treatment of choice for most forms of scoliosis It takes time and experience in many centres of the world to establish the reputation, indications and precise place for a new form of treatment

The available evidence suggests that the halo-pelvic apparatus is a powerful and effective method of correcting severe spinal deformities Because of the risk of pathological changes in the cervical spine its use should be restricted to those patients with deformities which cannot be effectively treated by the other methods in use today

SUMMARY

Part I

1) The history of the development of the halo-pelvic apparatus is discussed together with a general description of the apparatus The fitting of the apparatus is described in detail with emphasis laid on the accurate insertion of the pelvic pins, the use of the drilling jig and precise points of entry and exit in the iliac crest being the tubercle on the crest and the posterior superior iliac spine, respectively

2) During the post-operative period the four extension bars are placed connecting the patient s skull halo to the pelvic hoop For reasons of safety this is not done at the time of the fitting of the

Mechanical studies of the iliac crest confirmed that the bone in the region of the tubercle of the crest is stronger than in other regions of the bone, providing yet another reason why that area should be used for inserting the pelvic pins

plexus palsies in 3 per cent of the patients Temporary spasticity in the lower limbs occurred in the 3 per cent of patients A torn peritoneum occurred during insertion of the pelvic pins in one patient Laparotomy confirmed that no other damage had been done Although many patients had discharge associated with the pelvic pins, it was unusual for them to present clinical problems

Part III

9) In four patients with severe paralytic scoliosis a study was done to determine the amount of force which was transmitted through the spine by the halo-pelvic apparatus This was done by comparing force measurements on the halo-pelvic compression springs with the internal readings from the specially designed telemetry rod

Replacing the extension bars onto the halo and pelvic hoop at the end of posterior spinal surgery did not have a significant effect on the forces on the spine measured from the rod Lifting the patient from the operating table produced a mean force increase of 2 kp in the rod With acute distraction over 15 to 20 minutes a linear relationship was demonstrated between the externally applied force and the force simultaneously recorded on the telemetry rod in the spine The direct relationship between stress and strain was demonstrated confirming elasticity as one of the properties of biological tissue In the two patients who were assessed 60 per cent and 80 per cent, respectively, of changes in the externally applied force appeared as changes in the force measured in the spine by the telemetry rod

Part IV

10) With autopsy experimentation, using five and a half pound inches of force on the torque screw driver (0 06 kpm) the average skull pin penetrates 0 5 mm (average) of the outer table of the skull

Insertion of the pelvic pins is safe if a drilling jig and a carpenter's brace are used The ideal point of entry for the pin is at the tubercle of the crest or just inferior to this area, and the ideal exit point is the posterior superior iliac spine If a pin is inserted near the anterior superior spine it is likely to be intra-pelvic and therefore dangerous

APPENDIX A

SUMMARY OF CLINICAL MATERIAL

	TUBERCULOUS KYPHOSIS	KYPHOSCOLIOSIS			
Etiology	Tuberculous	Paralytic	Idiopathic	Congenital	Neurofibromato[illegible]
Number of patients	42	31	15	10	[illegible]
Age of onset of deformity (average)	1 5 yrs	2 yrs	14 yrs	birth	12 yrs
Age treatment commenced (average)	16 1 yrs (3 26 yrs)	14 1 yrs (6 25 yrs)	15 6 yrs (6 21 yrs)	12 8 yrs (6 19 yrs)	13 8 yrs (10 19 yrs)

This thesis is based on the following papers, which, in the text, will be referred to by *their Roman numerals*

I – Gunterberg, B., Norlén, L., Stener, B. & Sundin, T
Neurourologic evaluation after resection of the sacrum.
Accepted for publication in Investigative Urology

II – Gunterberg, B. & Petersén, I
Sexual function after major resections of the sacrum with bilateral or unilateral sacrifice of sacral nerves.
Submitted for publication in Fertility and Sterility

III – Gunterberg, B., Kewenter, J., Petersén, I. & Stener, B.
Anorectal function after major resections of the sacrum with bilateral or unilateral sacrifice of sacral nerves.
Submitted for publication in British Journal of Surgery

IV – Gunterberg, B., Romanus, B. & Stener, B.
Pelvic strength after major amputation of the sacrum.
An experimental study
Submitted for publication in Clinical Orthopaedics and Related Research.

CONTENTS

INTRODUCTION

The main indication for a major resection of the sacrum is a life threatening tumour. The symptoms of tumours in this region are often vague such as low-grade, sometimes periodic pain in the sacral region and only in advanced cases may there be more obvious disturbances like pressure on the rectum or impairment of lumbosacral nerve function, not seldom interpreted as being caused by disc protrusion. Thus, tumours in this area are often detected only when they have reached a considerable size, causing hesitation and irresolution when surgical treatment is considered.

The reasons for this are threefold: (1) expected technical difficulties during the operation, (2) doubts as to the postoperative function of the bladder, genitalia and anorectum and (3) uncertainty concerning the strength of the remaining sacroiliac regions.

Surgical procedures and factors limiting surgery in cases of tumours of the retrorectal or sacral regions are not well established. Not even in a modern handbook of surgery of the spine is sacral resection mentioned although both lumbar and coccygeal surgery are described (Rathke and Schlegel 1974). An abdominosacral approach is proposed by Freier et al. (1971) in the management of most retrorectal lesions greater than 5 cm in size, regardless of histological type. Steckler and Martin (1974) point out that the second sacral segment is the factor limiting the extent of resection since removal of this segment would lead to permanent and severe neurological damage. Resections more extensive than the three lower sacral segments are said to result in instability and collapse of the pelvis and descent of the lumbar spine (Pearlman and Friedman 1970). Nevertheless, Bowers (1948), MacCarty et al. (1952), Hays (1953), and Localio et al. (1967) have demonstrated the possibility of removal of the lower four segments of the sacrum and, in the case of Hays, even half the first sacral vertebra, without serious disabling consequences to pelvic stability. However, dislocation of the pubic symphysis was found in one of the cases reported by MacCarty et al., but this patient had a recurrence of fibrosarcoma only 2 months after discharge from hospital which might have influenced pelvic stability. Wilson (1972) has described a unilateral resection of the upper part of the sacrum, including the articular surfaces of the sacroiliac joint, with bridging of the gap with a bone graft consisting of the posterior third of the ipsilateral ilium. No insufficiency of the supporting function of the graft developed in this young patient.

INTRODUCTION

The main indication for a major resection of the sacrum is a life threatening tumour The symptoms of tumours in this region are often vague such as low grade, sometimes periodic, pain in the sacral region and only in advanced cases may there be more obvious disturbances like pressure on the rectum or impairment of lumbosacral nerve function, not seldom interpreted as being caused by disc protrusion. Thus, tumours in this area are often detected only when they have reached a considerable size, causing hesitation and irresolution when surgical treatment is considered

The reasons for this are threefold (1) expected technical difficulties during the operation, (2) doubts as to the postoperative function of the bladder, genitalia and anorectum, and (3) uncertainty concerning the strength of the remaining sacroiliac regions.

Surgical procedures and factors limiting surgery in cases of tumours of the retrorectal or sacral regions are not well established. Not even in a modern handbook of surgery of the spine is sacral resection mentioned although both lumbar and coccygeal surgery are described (Rathke and Schlegel 1974). An abdominosacral approach is proposed by Freier et al (1971) in the management of most retrorectal lesions greater than 5 cm in size regardless of histological type. Steckler and Martin (1974) point out that the second sacral segment is the factor limiting the extent of resection since removal of this segment would lead to permanent and severe neurological damage Resections more extensive than the three lower sacral segments are said to result in instability and collapse of the pelvis and descent of the lumbar spine (Pearlman and Friedman 1970). Nevertheless, Bowers (1948) MacCarty et al. (1952), Hays (1953), and Localio et al (1967) have demonstrated the possibility of removal of the lower four segments of the sacrum and in the case of Hays, even half the first sacral vertebra, without serious disabling consequences to pelvic stability However, dislocation of the pubic symphysis was found in one of the cases reported by MacCarty et al., but this patient had a recurrence of fibrosarcoma only 2 months after discharge from hospital which might have influenced pelvic stability Wilson (1972) has described a unilateral resection of the upper part of the sacrum, including the articular surfaces of the sacroiliac joint, with bridging of the gap with a bone graft consisting of the posterior third of the ipsilateral ilium. No insufficiency of the supporting function of the graft developed in this young patient.

In the case described by Bowers, as well as that reported by Hays and in four cases presented by Localio et al , all sacral nerves except for the first were sacrificed bilaterally In the two cases reported by MacCarty et al , in which the resection comprised the lower four sacral segments, curiously enough, only »the lower two or three sacral nerves were sacrificed bilaterally in one case and only the lower two sacral nerves in the other

The patients with bilateral loss of all sacral nerves except for the first had in the cases reported by Bowers and Hays definite urinary incontinence requiring a penile clamp or an incontinence bag, while in the cases described by Localio et al urinary function was described as »satisfactory» except in one patient who had stress incontinence and emptied the bladder with the help of abdominal wall contraction The patient presented by MacCarty et al , who possibly lacked the third in addition to the fourth and fifth sacral nerves bilaterally, had »satisfactory» urinary control but could not feel the urine being voided. The other patient, who lacked the lower two sacral nerves bilaterally, was »voiding normally» after a transurethral resection Cystometry was performed in two of the cases reported by Localio et al , revealing »good emptying» and »hypotonicity», respectively

The anorectal function in these eight patients described in the literature was evaluated only by history and described as adequate or satisfactory in four cases. Bowers' patient who had paralysis of the »rectal» sphincter managed his anorectal problem with a constipating diet One of the patients of MacCarty et al had poor rectal control Two patients had colostomy

The sexual function was not mentioned by any of the authors

During recent years a number of patients have been operated upon for tumour by Professor Bertil Stener, Head of the Department of Orthopædic Surgery II the Sahlgren Hospital, Goteborg, with major amputation or unilateral resection of the sacrum in several cases including substantial parts of adjacent iliac bone Radical tumour excision was always attempted which meant that the incision was carried through healthy tissues surrounding the tumour all the way Extreme care was taken not to sever the sacral nerves unnecessarily and thus the inevitable sacrifice of nerves was ascertained and recorded These cases led to the idea of investigating the consequences of the well-defined sacral nerve losses with reference to urinary, sexual and anorectal function The neurophysiology of the bladder, genitalia, and anorectum has been thoroughly studied by numerous authors Present knowledge is, however, partly based on animal experimentation, and it was thought that an investigation of these patients might contribute to a better understanding of the role of the sacral nerves as well as to confirmation of prevailing conceptions

Further, the question rose of to what degree the pelvic ring is weakened by a major amputation of the sacrum and what residual strength is retained in the posterior arch of the pelvis. Is there any risk of pelvic failure upon full weight bearing at an early stage postoperatively? A biomechanical study was therefore undertaken concerning pelvic strength after major sacral amputation.

The motor function of the lower extremities [redacted] our patients will not be presented in detail in this work. After sacral amputation no patient had any obvious impairment of the muscular function in the lower extremities referable to the operative sacrifice of sacral nerves. The leg function was impaired in three patients in whom a unilateral resection of the sacrum had been carried out. In one of these patients the sciatic nerve has been extirpated, in another the bone graft which [redacted] bridging the gap after an extensive sacroiliac resection does not yet permit full weight bearing, and in the third hemipelvectomy has been done along with the sacral resection.

In cases of tumours necessitating sacral resection to varying extent it is as a rule possible, by preoperative examinations of various kinds, and careful planning, to calculate the necessary sacrifice of nerves and skeletal parts. Therefore, through our studies, we hoped to be able to collect data permitting, for example, prediction of the degree of urogenital and anorectal disability and the risks of standing and walking with full weight-bearing that these patients would encounter postoperatively.

In the case described by Bowers, as well as that reported by Hays and in four cases presented by Localio et al , all sacral nerves except for the first were sacrificed bilaterally In the two cases reported by MacCarty et al , in which the resection comprised the lower four sacral segments, curiously enough, only »the lower two or three sacral nerves» were sacrificed bilaterally in one case and only the lower two sacral nerves in the other

The patients with bilateral loss of all sacral nerves except for the first had in the cases reported by Bowers and Hays definite urinary incontinence requiring a penile clamp or an incontinence bag, while in the cases described by Localio et al urinary function was described as »satisfactory» except in one patient who had stress incontinence and emptied the bladder with the help of abdominal wall contraction The patient presented by MacCarty et al , who possibly lacked the third in addition to the fourth and fifth sacral nerves bilaterally, had »satisfactory» urinary control but could not feel the urine being voided. The other patient, who lacked the lower two sacral nerves bilaterally, was »voiding normally» after a transurethral resection Cystometry was performed in two of the cases reported by Localio et al , revealing »good emptying» and »hypotonicity», respectively

The anorectal function in these eight patients described in the literature was evaluated only by history and described as adequate or satisfactory in four cases Bowers' patient who had paralysis of the »rectal» sphincter managed his anorectal problem with a constipating diet One of the patients of MacCarty et al had poor rectal control Two patients had colostomy

The sexual function was not mentioned by any of the authors

The sexual function was not mentioned by any of the authors.

During recent years a number of patients have been operated upon for tumour by Professor Bertil Stener, Head of the Department of Orthopædic Surgery II, the Sahlgren Hospital, Göteborg, with major amputation or unilateral resection of the sacrum, in several cases including substantial parts of adjacent iliac bone. Radical tumour excision was always attempted which meant that the incision was carried through healthy tissues surrounding the tumour all the way. Extreme care was taken not to sever the sacral nerves unnecessarily and thus the inevitable sacrifice of nerves was ascertained and recorded. These cases led to the idea of investigating the consequences of the well-defined sacral nerve losses with reference to urinary, sexual and anorectal function. The neurophysiology of the bladder, genitalia and anorectum has been thoroughly studied by numerous authors. Present knowledge is, however, partly based on animal experimentation, and it was thought that an investigation of these patients might contribute to a better understanding of the role of the sacral nerves as well as to confirmation of prevailing conceptions.

trusor part of the bladder mucosa is said to be supplied mainly by thoracolumbar and the trigone predominantly by sacral afferents. The existence of thermaesthesia of the bladder mucosa is the subject of controversy.

The sex act

The events of the sex act are comparable in both sexes if the embryological development of the respective structures is taken into account. *Erection* of the penis in the male, analogous to the tumescence of the clitoris and labiae minorae in the female, is brought about by psychogenic and/or reflexogenic stimuli which accomplish arterial dilatation in the corpora. The impulses are mediated by the parasymphathetic pelvic nerves (S 2 - S 4). In addition, sympathetic impulses from thoracolumbar segments may be responsible as has been shown in animals and confirmed by clinical findings. *Emission* of semen in the male by contraction of the vasa and seminal vesicles corresponds in the female to the contraction of the smooth musculature of the tubes and uterus and the expulsion of the contents of the glands of Skene. It is dependent on impulses travelling in the fibres of the sympathetic thoracolumbar outflow. *Ejaculation* in the male corresponds in the female to rythmic contractions of the musculus sphincter cunni (the equivalent of the ischiocavernosus and bulbocavernosus muscles in the male). Emission triggers off afferent impulses from the prostatic and membranous urethra travelling in the pudendal and possibly pelvic nerves to the sacral cord (S 2 - S 4) where they elicit efferent impulses mediated by the pudendal nerves, which effect clonic contractions of the pelvic floor muscles. The smooth muscles of the vesical neck contract in response to efferent impulses from thoracolumbar segments to prevent regurgitation of the ejaculate into the bladder. *Detumescence* of the corpora in the male and the clitoris and labiae in the female is accomplished by sympathetic impulses causing vasoconstriction. *Orgasm* precedes and accompanies emission and ejaculation. It may be retained in one form or another as long as either the autonomic innervation of the adnexa or the somatic innervation of the pelvic floor musculature remains intact.

Faecal continence and defaecation

Continence depends partly on the configuration of the anorectal region and partly on the action of muscles. The main factors are the angulation between the rectum and the anal canal, maintained by the pull of the puborectalis muscle (innervated by the pudendal nerves, S 2 - S 4), the anteroposterior slit of the anal canal which accounts for a »flutter valve« mechanism, and the tonic activity of the internal anal sphincter (excitatory impulses via the hypogastric nerves and inhibitory impulses through the parasympathetic pelvic nerves). Additional support is provided by the external anal sphincter (innervated by the pudendal nerves) whose main function is to give emergency protection voluntarily for up to one minute. The entry of faeces from the sigmoid colon

CLINICAL STUDIES
ON UROGENITAL AND ANORECTAL FUNCTION

Brief reviews of relevant present concepts on urogenital and anorectal function with special reference to segmental innervation

Several textbooks and reviews on these concepts have been published and the reader is referred to these for further details (e g Bors and Comarr 1960, Schuster 1968, Kerremans 1969, Hotchkiss 1970, Bors and Comarr 1971, Duthie 1971, Carlsson and Sundin 1974).

Urinary continence and voiding

The anatomical arrangement of the structures round the bladder neck provides a »passive» continence mechanism. The striated pelvic floor muscles, including the external urethral sphincter, innervated by the pudendal nerves (S 2 - S 4), are necessary for this continence only during brisk increases of the intraabdominal pressure, as for instance during coughing »Active» continence, which means voluntary inhibition of micturition, is achieved by contraction of the external urethral sphincter The mechanism of adaptation of the bladder wall during bladder filling, i e how an increase in the bladder pressure is counteracted, has not been fully explored At moderate and large bladder volumes adaptation is thought to be achieved via afferent impulses in the pelvic nerves and efferent inhibitory impulses in the sympathetic hypogastric nerves (T 11 - L 2), bringing about a bladder relaxation During filling of the bladder a first sensation of fulness is experienced at about half the bladder capacity and a desire to void when the bladder is nearly full These sensory impulses are mediated via the pelvic nerves Micturition may be voluntarily suppressed or facilitated In the latter case a co-ordinated reflex activity is elicited so that the distension of the detrusor, which initiates its con traction (the micturition reflex), is accompanied by relaxation of the striated muscles of the urethra. The micturition reflex has its afferent and efferent pathways in the pel vic nerves (S 2 - S 4) while the relaxation of the urethral striated muscles is brought about through pelvic afferents and pudendal efferents The co-ordination of afferent and efferent impulses of both autonomic and somatic systems at conscious and subconscious levels is responsible for the ability of the adult human to inhibit and initiate voiding irrespective of the degree of bladder filling Receptors in the bladder mucosa are able to recognize painful but not tactile stimulation The afferent pathways mediating pain impulses from the bladder have not been established with certainty The de-

into the rectum causes sensory stimulation [illegible]

[illegible] ... to the

[illegible] anal sphincter relax [illegible]

[illegible]

[illegible] nerves and efferent in the pudendal nerves). If the fæces entering the rectum are small the basal activity of the sphincters is restored and the individual is no longer conscious of the contents in the ampulla. Further filling of the rectum evokes stronger sensory stimulation experienced as a need to defæcate. Eventually the internal sphincter becomes constantly relaxed and the basal activity of the external sphincter is depressed leaving voluntarily induced contraction responsible for the closure of the anal canal. The closure of the anal canal permits build-up pressures within the rectum so that subsequent sphincteric inhibition results in expulsion of stools, facilitated by rectal contraction (efferent fibres in the pelvic nerves). When emptying is complete a rebound contraction of the anal sphincters occurs.

MATERIAL

Altogether ten patients were studied, six with bilateral and four with unilateral sacrifice of sacral nerves (Table I). The nerves were identified and cut during operations for radical extirpation of tumours in the sacrum or its vicinity. In no patient has any sign of local tumour recurrence been observed.

Studies of urinary and sexual function were carried out in nine patients and studies of anorectal function in seven. Details of diagnosis, sex, age, investigations performed, and postoperative time in years are given in Table I.

METHODS

Urinary function (I)

After taking the patient's history the following studies were carried out: clinical examination, cystometry, cystoscopy including testing of the sensibility of the bladder and urethra, intravenous pyelography and urinary culture.

For cystometry two plastic catheters (sonde a nutrition K-32, no. 5 Fr., Pharmaseal) were introduced into the bladder through the urethra. Isotonic saline at room temperature was infused at a rate of about 50 ml per min through one of the catheters. The other catheter was connected, via a pressure receptor and an amplifier, to a kymograph (Mingograf, Elema-Schonander), providing a continuous recording of the intravesical pressure. The pressure receptor was placed at a level of 5 cm below the pubic symphysis to avoid negative pressure recordings. The intrarectal pressure was recorded

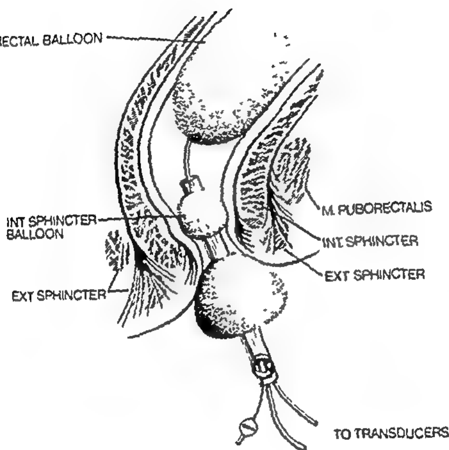

Fig. 1. Schematic drawing of the pressure-sensing device in the rectum and the anal canal. Distension of the rectal balloon provides the stimulus for reflex responses from the internal and external sphincters. Separate pressures are obtained from the rectal balloon and the internal sphincter balloon. The external balloon was used as an aid to keep the device in place.

continuously via a balloon catheter. This pressure was electronically subtracted from the intravesical pressure. The pressure increase caused by an intra abdominal pressure increase was thereby eliminated, and in the subtraction curve the »true» intravesical pressure was recorded. Early during bladder filling the calibration of the rectal pressure was changed so as to give an exact elimination in the subtraction curve of a pressure increase caused by straining. Thus, the numerical value of the rectal pressure cannot be considered as correct.

The sensibility of the bladder mucosa was tested only by electrocoagulation in the patients with bilateral loss of sacral nerves. In the patients with unilateral loss of sacral nerves a more elaborate investigation of the sensibility of the bladder mucosa was performed. Thus, the sensibility of the mucosa was tested by electrocoagulation, light touch with a ureteral catheter and by forcing the catheter more vigorously against the bladder wall. When thermæsthesia was tested the bladder was filled with 200 - 300 ml of physiological saline at room temperature. Then 10 - 15 ml saline at 0°C or +60°C, was injected as a jet against the bladder wall through a ureteral catheter with an end-hole, introduced into the bladder through a cystoscope. In all patients the sensibility of the urethra was tested only by pin pricking.

Sexual function (II)

The history was taken by personal interview and a questionnaire. Skin sensibility and the sensibility of the glans penis were tested by touching with cotton wool and pin-pricking. The male patients, except for one who refused, were also submitted to an electromyographic investigation in attempt to record myoelectric signals from the external urethral and anal sphincters during ejaculation.

For the electromyographic study the patient was placed in a modified lithotomy position after having emptied his bladder. Co axial needle electrodes of 0.5 mm external diameter were inserted percutaneously into the striated urethral and anal sphincters according to a technique described previously (Petersén and Stener 1970). The positioning of the needles was monitored by an oscilloscope and a loud speaker connected to the electromyograph. A three channel type Disa electromyograph was used for the registration. When the electrodes were in place the subject was left in solitude to bring about ejaculation by masturbation. Of the four patients investigated only one could bring about ejaculation (no. 8). The electromyographic investigation was not repeated in the failure cases.

Anorectal function (III)

The history was taken. The sphincter tone was estimated by palpation. The anal reflex (contraction of the anal sphincter on drawing a needle across the perianal skin) was

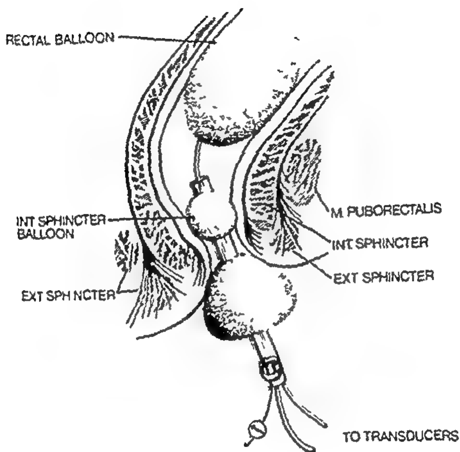

Fig. 1. Schematic drawing of the pressure-sensing device in the rectum and the anal canal. continuously via a balloon catheter This pressure was electronically subtracted from the intravesical pressure The pressure increase caused by an intra abdominal pressure increase was thereby eliminated, and in the subtraction curve the »true» intravesical pressure was recorded Early during bladder filling the calibration of the rectal pressure was changed so as to give an exact elimination in the subtraction curve of a press ure increase caused by straining Thus, the numerical value of the rectal pressure cannot be considered as correct

The sensibility of the bladder mucosa was tested only by electrocoagulation in the patients with bilateral loss of sacral nerves In the patients with unilateral loss of sacral nerves a more elaborate investigation of the sensibility of the bladder mucosa was per formed Thus, the sensibility of the mucosa was tested by electrocoagulation, light touch with a ureteral catheter and by forcing the catheter more vigorously against the bladder wall When thermæsthesia was tested the bladder was filled with 200 300 ml of physiological saline at room temperature Then 10 15 ml saline at 0°C or +60°C, was injected as a jet against the bladder wall through a ureteral catheter with an end hole, introduced into the bladder through a cystoscope In all patients the sensibility of the urethra was tested only by pin pricking

Sexual function (II)

The history was taken by personal interview and a questionnaire Skin sensibility and the sensibility of the glans penis were tested by touching with cotton wool and pin pricking The male patients except for one who refused were also submitted to an electromyographic investigation in attempt to record myoelectric signals from the ex ternal urethral and anal sphincters during ejaculation

For the electromyographic study the patient was placed in a modified lithotomy position after having emptied his bladder Co axial needle electrodes of 0 5 mm external diameter were inserted percutaneously into the striated urethral and anal sphincters according to a technique described previously (Petersén and Stener 1970) The posi tioning of the needles was monitored by an oscilloscope and a loud speaker connect ed to the electromyograph A three channel type Disa electromyograph was used for the registration When the electrodes were in place the subject was left in solitude to bring about ejaculation by masturbation Of the four patients investigated only one could bring about ejaculation (no 8) The electromyographic investigation was not repeated in the failure cases.

Anorectal function (III)

The history was taken The sphincter tone was estimated by palpation The anal reflex (contraction of the anal sphincter on drawing a needle across the perianal skin) was

sensation could not be obtained the balloon was filled with a maximum of 500 ml. T rectal balloon was then emptied in the same stepwise manner. During the whole proc dure pressure recordings from the rectal balloon and the balloon placed in the anal canal were made as well as electromyograms from the external anal sphincter. Pressu volume curves (rectometrograms) were constructed for each patient. This was done b subtracting the pressures of the rectal balloon obtained at various volumes in free air from the pressures obtained at the same volumes with the balloon in the ampulla rec as described by Ihre (1974)

RESULTS

Bilateral loss of sacral nerves (I, II, III)

S 4, S 5

This patient (no 1) had slight urinary stress incontinence and used a diaper Cystometry revealed detrusor activity She had no residual urine Cystoscopic findings we normal as also were sensibility tests of the bladder and urethra. The pyelogram was without pathological changes. Urinary culture was positive (>100 000 bacteria/ml).

The patient considered her sexual function to be normal and enjoyed sexual interco regularly She had not experienced any postoperative change of sexual perception o orgasm. The sensibility of the labiae was normal.

In this patient the rectum had been extirpated

S 3, S 4, S 5

Of these two women one had an indwelling catheter (Patient no 3). The other had strain to empty her bladder No micturition contraction was recorded in the cystom rograms. The residual urine volume was 90 ml in the patient without a catheter Cy: scopy revealed slight trabeculation Painful stimuli to the mucosa of the bladder an urethra were not perceived The pyelograms were normal One of these patients had urinary tract infection (no 3).

The younger of these two patients (no 2) reported no change of sexual behaviour c perception postoperatively and considered her sexual function to be normal. The ol er patient had all her life experienced minimal perception upon sexual stimulation b still had intercourse, although unfrequently She did not recognize any alteration p operatively The sensibility of the labiae was normal in these two patients.

Anorectal function was studied in the older patient (no 3). She had no sense of defecatory need Soiling occurred The patient used laxatives and visited the toilet ev

tested bilaterally by observation. The sensibility of the anal canal, below the dentate line, and perianal skin was tested by tactile, painful and thermal stimuli. The rectum and internal anal sphincter were investigated with a pressure recording device (Fig. 1) suggested by Schuster et al. (1965). Electromyography of the external anal sphincter was made on both the left and the right side simultaneously with the pressure recordings. Thus, the relationships between rectal volumes and pressures, pressure changes in the internal sphincter region and the myoelectric activity in the external sphincter were established.

The pressure recording device consisted of a hollow metal cylinder (external diameter 7 [illegible] that sn [illegible] (Grass Model 7 II Polygraph, paper speed used 50 mm per min) while the outer balloon was used to keep the device in place. A third balloon of thin latex (5 cm long, 2 cm wide when inflated with 10 ml of water) was inserted through the hollow core of the recording device and was also connected via polyethylene tubing to the pressure recording unit. The pressure receptor was placed at the level of the anal orifice.
The myoelectric activity of the external anal sphincter was picked up by concentric needle electrodes (Disa) of 0.65 mm diameter. The signals were amplified on a Disa electromyograph and recorded on tape using an FM tape-recorder (Philips Ana-log 7). Graphic recordings were obtained by means of an ink-jet recorder (Mingograf, Siemens-Elema) at a reduced tape speed playback. The quantitative signal analysis was performed on an analyzer (Örtengren 1975) entailing continuous recordings of the fullwave rectified and smoothed, »integrated», total signal. The output from the detector was presented on a logarithmic, decibel scale with arbitrary reference

Procedure

The needle electrodes were placed bilaterally in the external anal sphincter with the patients in the lithotomy position. Recordings were made of the spontaneous myoelectric activity, during voluntary contraction of the sphincter, and during coughing. The thin latex balloon was then placed in the ampulla recti and the hollow metal cylinder with its two surrounding balloons was inserted into the anal canal so that the internal balloon when inflated with 4 ml of water (+37°C) was surrounded by the internal anal sphincter. The external balloon,used for keeping the device in place, was inflated with 15 ml of air. The rectal balloon w[illegible] straightened out by filling it with a small volume of water which was then removed. The registrations then started and the rectal balloon was filled with 20 ml of water (+37°C) followed by a further 30 ml after approximately 30 seconds. The rectal balloon was then intermittently filled with 50 ml of water every 30 - 60 seconds until the patient reported an almost intolerable sensation, i.e. the maximum tolerable volume was reached. In cases in which such a

S2, S3 S4 S5

Urinary function was studied in the male patient (no. 5). He had undergone a transurethral bladder neck resection postoperatively. He was incontinent and wore an incontinence bag and had to strain when he wished to empty his bladder. No micturition contraction was observed in his cystometrogram. Residual urine was 50 ml. Cystoscopy revealed trabeculation. There was loss of bladder and urethral sensibility. Pyelography was normal. Urinary culture was positive.

Sexual function in this man was impaired. He had weakened libido but enjoyed sexual intercourse a few times a month. Erection occurred exclusively upon psychical stimulation and was somewhat weaker than preoperatively but sufficient to permit intercourse. »Ejaculation» was of a dripping nature. The sensation of orgasm was altered and not referred to the penis and perineum as it had been before the onset of the tumour disease. The penis and glans were anaesthetic.

Anorectal function was studied in the female patient (no. 6). She was incontinent and constipation was her only safeguard against soiling. Defaecatory need was not experienced normally and she was unable to recognize faecal quality in the anal canal. Sphincter tone was lacking on palpation. The anal reflex was not observed. The anal region was anesthetic. The patient became aware of rectal distension at volumes of 300 ml (71 mm Hg) and when the rectal balloon had been filled to 400 ml or more it tended to protrude outside the anus without the patient being conscious of this. The internal anal sphincter reacted with transient relaxations on stepwise rectal balloon filling and became continuously depressed at a volume of 250 ml (50 mm Hg). Electromyograms from the external anal sphincter displayed denervation potentials only. No external anal inflation reflex could be observed, nor was there any voluntarily induced myoelectric activity.

Unilateral loss of sacral nerves (I, II, III)

S2 S3 S4 S5 and S1 S2 S3 S4 S5

Essentially the same findings were recorded in these four patients. Their urinary function was subjectively unimpaired. Micturition contractions were registered in the cystometrograms although the patients had to strain at the end of micturition. The residual volumes were 10 - 15 ml. The cystoscopy findings were essentially normal. Bladder wall sensibility tests revealed that light touch with a ureteral catheter could not be felt on either side. When the catheter was forced more vigorously against the bladder wall this caused pain on the intact side and diffuse discomfort on the other side, in the latter case with poor ability of lateralization. When testing the thermaesthesia, the jets of cold or hot saline were correctly recognized on the intact side but could not be felt on the denervated side. Coagulation of the mucosa of the bladder and trigone was felt as

day at the same time to evacuate her rectum. She needed a diaper. Sphincter tone judged by palpation was decreased. The anal reflex was absent. The sensibility of the anal region was decreased with respect to tactile and painful stimulation, and lacking as regards thermal stimulation. The patient became continuously conscious of rectal distension at a volume of 350 ml (87 mm Hg) The rectum had a maximum tolerable volume of at least 500 ml (>105 mm Hg). She felt a dull, uncomfortable sensation in the lower abdomen at these substantial rectal volumes. The internal anal sphincter reacted with transient relaxations on stepwise rectal balloon filling and became continuously depressed at a volume of 200 ml (46 mm Hg) EMG revealed weak spontaneous activity in the external anal sphincter Attempts to contract the sphincter voluntarily resulted in a small increase of the myoelectric activity Denervation potentials were recorded in the electromyogram. The external anal inflation reflex (transient contraction of the external anal sphincter at rectal distension) was not observed. The weak spontaneous myoelectric discharge disappeared at a rectal volume of 400 ml (105 mm Hg).

Right side S 3, S 4, S 5. Left side S 2, S 3, S 4, S 5

This patient (no. 4) had urinary stress incontinence He wore a diaper and had to strain when he wished to empty his bladder No micturition contraction was observed in his cystometrogram. The residual urine volume was 15 ml Cystoscopy revealed trabeculation of the bladder wall Bladder wall sensibility was absent Pyelography was normal Urinary culture was negative

Sexual function was altered postoperatively Libido was preserved but erection weakened and insufficient for intercourse Ejaculation occurred nightly with an orgasm-like sensation The sensibility of the left side of the penis and glans was heavily diminished

There was fæcal incontinence if rectal contents were not solid Defæcatory need was never experienced as it had been preoperatively The patient was unable to discriminate between different qualities of rectal contents at defæcation, which was brought about by straining or by pressure on the rectum from behind Sphincter tone judged by palpation was decreased The anal reflex was absent The sensibility of the anal region was abolished concerning all modalities on the left side and the posterior quadrant of the right side, it was weak on the anterior quadrant of the right side The patient became continuously conscious of rectal distension at a volume of 300 ml (32 mm Hg) and had a maximum tolerable volume of at least 500 ml (60 mm Hg) The internal anal sphincter reacted with transient relaxations on stepwise rectal balloon filling and became continuously depressed at a volume of 300 ml (32 mm Hg) The external sphincter displayed weak spontaneous myoelectric activity bilaterally and presence of denervation potentials. A small increase of the myoelectric activity was recorded on voluntary contraction bilaterally. The external anal inflation reflex was absent. The weak spontaneous discharge decreased but did not disappear as the rectum was progressively distended.

S2, S3, S4 S5

Urinary function was studied in the male patient (no 5). He had undergone a transurethral bladder neck resection postoperatively He was *incontinent* and wore an in *continence* bag and had to strain when he wished to empty his bladder No micturition contraction was observed in his cystometrogram. Residual urine was 50 ml Cystoscopy revealed trabeculation There was loss of bladder and urethral sensibility Pyelography was normal Urinary culture was positive

Sexual function in this man was impaired He had weakened libido but enjoyed sexual intercourse a few times a month. Erection occurred exclusively *upon psychical stimu lation* and was somewhat weaker than preoperatively but sufficient to permit inter course Ejaculations was of a dripping nature The sensation of orgasm was altered and not referred to the penis and perineum as it had been before the onset of the tumour disease The penis and glans were anaesthetic.

Anorectal function was studied in the female patient (no 6). She was incontinent and *constipation was her only safeguard against soiling.* Defaecatory need was not experienced normally and she was unable to recognize faecal quality in the anal canal Sphincter tone was lacking on palpation The anal reflex was not observed The anal region was anaesthetic The patient became aware of rectal distension at volumes of 300 ml (71 mm Hg) and when the rectal balloon had been filled to 400 ml or more it tended to protrude outside the anus without the patient being conscious of this. The internal anal sphincter reacted with transient relaxations on stepwise rectal balloon filling and became continuously depressed at a volume of 250 ml (50 mm Hg) Electromyograms from the external anal sphincter displayed denervation potentials only No external anal inflation reflex could be observed nor was there any voluntarily induced myoelectric activity

Unilateral loss of sacral nerves (I II III)

S2 S3 S4 S5 and S1 S2 S3 S4 S5

Essentially the same findings were recorded in these four patients. Their urinary function was subjectively unimpaired Micturition contractions were registered in the cystometrograms although the patients had to strain at the end of micturition. The residual volumes were 10 15 ml The cystoscopy findings were essentially normal. Bladder wall sensibility tests revealed that light touch with a *ureteral catheter could not be felt* on either side When the catheter was forced more vigorously against the bladder wall this caused pain on the intact side and diffuse discomfort on the other side, in the latter case with poor ability *of lateralization.* When testing the thermaesthesia, the jets of cold or hot saline were correctly recognized on the intact side *but could not be felt* on the denervated side Coagulation of the mucosa of the bladder and trigone was felt as

pain on the intact side. On the denervated side such stimuli were not felt in the bladder, nor was pin pricking felt in the urethra. Pyelography was normal except in Patient no. 8, who had right-sided hydronephrosis and hydroureter owing to postoperative fibrosis. This patient was later operated upon with reimplantation of the right ureter into the bladder. Urinary culture was positive in Patient no. 9.

The sexual function of these patients was subjectively unimpaired. The quality and degree of the reactions of the external genitalia was unchanged as also was the degree of sexual satisfaction. There was loss of sensibility on the denervated side of the penis and labiæ. EMG was recorded from the external urethral and anal sphincters in one of the male patients (no. 8) during ejaculation Clonic contractions of both sphincters occurred alternately

The anorectal function was also subjectively unimpaired and ability to recognize different qualities of rectal contents in the anal canal was present. Sphincter tone, judged by palpation, was normal The anal reflex could be elicited on the intact side but not on the denervated side The sensibility of the anal region was unimpaired on the intact side, but there was anæsthesia concerning tactile and thermal stimuli on the denervated side. Painful stimuli on this side were recognized as a weak, unpleasant sensation localized to the midline or intact side The patients became continuously conscious of rectal distension at volumes of 150 - 200 ml (18 - 34 mm Hg) and had maximum tolerable volumes of 200 - 350 ml (36 - 52 mm Hg) The internal sphincters reacted with transient relaxations on stepwise rectal balloon filling and became continuously depressed at rectal volumes of 100 - 200 ml (18 - 43 mm Hg) The external anal sphincter displayed spontaneous myoelectric activity bilaterally and there was strong increase of this activity bilaterally on voluntary contraction During prolonged contraction (about 30 seconds) the strongly increased activity was maintained bilaterally The external anal inflation reflex was observed bilaterally in three of these patients, in one (no 10) the presence of the reflex was doubtful Reflex decrease or inhibition of external sphincter activity was recorded at maximum tolerable volumes

DISCUSSION

Bladder and urethra

The micturition reflex in the cystometrogram was not abolished by sacrifice of the fourth and fifth sacral nerves bilaterally, but it was abolished if the third sacral nerves were sacrificed as well This indicates that the second sacral segment alone cannot subserve the micturition reflex and is in accordance with the observations of Markland et al. (1972) that the main motor axons of the pelvic parasympathetic nerves arise in the third and fourth sacral segments. The cystometrograms of the patients with unilateral

sacral denervation revealed detrusor activity, although these patients had to strain toward the end of micturition in order to empty their bladders. This is in agreement with the findings of several authors who in patients with lumbosacral dysraphic states with unilateral neurological impairment found normal bladder function (e g. Ericsson et al. 1970)

The unilaterally denervated patients offered a unique possibility to investigate unsettled questions concerning bladder sensibility Thus, detrusor mucosal pain is said to be mediated by spinal segments as high up as the L 1 to T 12 levels (Bors and Comarr 1971). Our patients with unilateral sacral denervation were unable to feel pain on the denervated side when the bladder mucosa was electrocoagulated They could, however, feel stretching of the bladder wall on the denervated side, which is in agreement with the findings of Talaat (1937) who recorded afferent impulses from the hypogastric nerves upon distension of the bladder in dogs Several authors (Senger and Rothfeld 1947, Nathan 1952, Bors et al. 1956) have found no thermaesthesia of the bladder mucosa and state that this sense is confined to the urethra. Pitfalls in the investigation of bladder thermaesthesia and the ability to lateralize thermal stimuli are, firstly, that temperature changes of the cystoscope or of the whole bladder content may be mediated via urethral nerves, secondly, that the stimulus might induce local detrusor contraction, making it possible to lateralize it, and thirdly, that the jet of hot or cold saline might evoke the lateralized sensation purely by mechanical stimulation of receptors. However, with the latter technique used in the present study (I) the differentiation of heat and cold and the ability to lateralize must have been conveyed in nerves from the bladder mucosa since the unilaterally denervated patients could not feel thermal stimuli at all on the denervated side of the bladder, but could recognize heat and cold on the intact side Moreover the jet was not felt on either side when the injection was made with saline at room temperature with the same force on both sides. The experiments thus indicate that the bladder mucosa has thermaesthesia which is most probably conveyed by the parasympathetic pelvic nerves. This is in agreement with the findings of e g Ray and Neill (1947), Retief (1950) and McDonald and Murphy (1959) Thermaesthesia seems, however, less well developed in the bladder mucosa than in the skin or oral mucosa, which might account for the divergent findings of different investigators

Genitalia

The sexual function was unaltered in the three women with bilateral loss of the fourth and fifth or third, fourth and fifth sacral nerves. The sensibility of the labiae appears to be mediated above the level of S 3 since both the patients who lacked the third sacral nerves had normal sensibility The sensibility of the penis seems to be subserved mainly by the second sacral nerve. Patient no. 4 had normal sensibility on the right side

of the penis where this nerve had been spared, but strongly diminished sensibility on the left side where only the first sacral nerve was left Patient no 5 who lacked the second sacral nerve on both sides had an anaesthetic penis. This is in agreement with the findings of Bohm et al (1956) who found unilateral impairment of cutaneous sensibility of the penis after selective sectioning of one dorsal root of S 2, performed in seven men

In the male, the preservation of only the first sacral nerve on both sides is compatible with sexual activity such as reported by Patient no 5, who had exclusively psychogenic erection, dripping »ejaculation», and orgasmic sensation referred to the lower abdomen This case parallels one reported by Bernhardt (1888), who described the same condition in a young man with a traumatic lesion of the spinal cord with anaesthesia of the four lower sacral dermatomes Purely psychogenic erections are known to occur in about 30 per cent of paraplegics with lower motor neuron lesions (Bors and Comarr 1960)

In the patients with total loss of sacral nerves on one side the sex act was experienced as essentially unaltered although there was unilateral anaesthesia of the penis or labiæ The EMG from Patient no 8 during ejaculation displayed the normal event of clonic contraction bilaterally of the external urethral and anal sphincters (Petersén and Stener 1970), although the contractions of the two sphincters alternated which is not the case in normal subjects We can offer no explanation of this phenomenon in our patient

Rectum and anus

Normal anorectal function, like normal bladder function, appears to be dependent on the preservation of at least one third sacral nerve as the patients who lacked this nerve on both sides were incontinent with respect to soft fæces Moreover, these patients had difficulty in expelling solid stools When the second sacral nerve had been spared painful and tactile stimuli could be weakly perceived in the anal canal This sensibility of the anal canal, however, was not sufficient for recognition of the quality of stools passing the canal The sensory perceptions from the anal canal thus seem to be mediated mainly in nerves below the S 2 level The patient with only the first sacral nerves left bilaterally was anaesthetic in the anal region

There was also impaired sensibility concerning rectal wall distension in the three patients with bilateral loss of sacral nerves and it may be concluded that the sensation of rectal wall distension is also to a large extent mediated via segments below the S 2 level

In all seven patients who where subjected to the study of anorectal function, the internal anal sphincter displayed the normal events of relaxation as the rectum was distended – the internal anal inflation reflex – indicating that this is not a spinal reflex at the S 2 - S 5 levels. Denny Brown and Robertson (1935) have reported the presence of this internal sphincter reflex in a patient with destruction of the sacral cord and in another patient with sectioned hypogastric nerves. The pathways of the reflex are unknown but an intact anorectum seems necessary (Gaston 1948, Schuster et al. 1963). Several authors (e.g. Denny Brown and Robertson 1935, Schuster 1975) have suggested an intramural pathway which is well compatible with our findings.

The external anal sphincter also seems to be dependent to a large extent on the preservation of sacral nerves below the S 2 level, as the spontaneous myoelectric activity of this sphincter was weak in Patient no. 3, who had the second sacral nerve left on both sides, and in Patient no. 4, who had this nerve left on one side. In addition, denervation potentials were registered in these patients. In Patient no. 6, who had only the first sacral nerves left, no spontaneous activity was present in the external sphincter except for a few denervation potentials. A small increase of the myoelectric activity during attempts to contract the sphincter voluntarily was seen in the patients who had one or both second sacral nerves left. This weak sphincter contraction was, however, without obvious significance for the anorectal function. No transient reflex contraction of the external sphincter during rectal wall distension – the external anal inflation reflex – was observed in the patients with bilateral nerve sacrifice, indicating that this reflex is mediated below the S 2 level.
Unilateral sacral denervation did not imply any significant impairment of anorectal function. There was, however, a loss of sensibility on the denervated side, although this was of no significance for recognizing the quality of the rectal contents when they passed the anal canal. The sense of rectal distension seemed normal as also did the reflex pattern of the internal anal sphincter. The spontaneous activity of the external anal sphincter was of good quality bilaterally, but in some of the electromyograms a slight difference of activity between intact and denervated sides could be observed. On brisk voluntary contraction there was an essentially normal increase of myoelectric activity bilaterally and this increased activity could be maintained on prolonged voluntary contraction as may be expected in normal subjects (Kadefors and Petersén 1970). This strongly suggests an overlap distribution of motor fibres from the right and left pudendal nerves and proves the sufficiency of only unilateral innervation of the external anal sphincter. The investigations of Sherrington (1892) and Bishop (1959), who in animals produced contraction of the entire anal circumference with unilateral pudendal nerve stimulation, were thus confirmed.

Several different aspects of anorectal function were studied. The significance of any of these factors per se for continence or defecation, however, can not be evaluated

of the penis where this nerve had been spared, but strongly diminished sensibility on the left side where only the first sacral nerve was left. Patient no 5 who lacked the second sacral nerve on both sides had an anaesthetic penis This is in agreement with the findings of Bohm et al. Moreover, these patients had difficulty in expelling solid stools When the second sacral nerve had been spared painful and tactile stimuli could be weakly perceived in the anal canal This sensibility of the anal canal, however was not sufficient for recognition of the quality of stools passing the canal The sensory perceptions from the anal canal thus seem to be mediated mainly in nerves below the S 2 level The patient with only the first sacral nerves left bilaterally was anaesthetic in the anal region

There was also impaired sensibility concerning rectal wall distension in the three patients with bilateral loss of sacral nerves and it may be concluded that the sensation of rectal wall distension is also to a large extent mediated via segments below the S 2 level

In all seven patients who where subjected to the study of anorectal function, the internal anal sphincter displayed the normal events of relaxation as the rectum was distended – the internal anal inflation reflex – indicating that this is not a spinal reflex at the S 2 - S 5 levels. Denny Brown and Robertson (1935) have reported the presence of this internal sphincter reflex in a patient with destruction of the sacral cord and in another patient with sectioned hypogastric nerves. The pathways of the reflex are unknown but an intact anorectum seems necessary (Gaston 1948, Schuster et al. 1963) Several authors (e g. Denny-Brown and Robertson 1935, Schuster 1975) have suggested an intramural pathway which is well compatible with our findings.

The external anal sphincter also seems to be dependent to a large extent on the preservation of sacral nerves below the S 2 level, as the spontaneous myoelectric activity of this sphincter was weak in Patient no 3, who had the second sacral nerve left on both sides, and in Patient no 4, who had this nerve left on one side In addition, denervation potentials were registered in these patients. In Patient no 6, who had only the first sacral nerves left, no spontaneous activity was present in the external sphincter except for a few denervation potentials A small increase of the myoelectric activity during attempts to contract the sphincter voluntarily was seen in the patients who had one or both second sacral nerves left This weak sphincter contraction was, however, without obvious significance for the anorectal function No transient reflex contraction of the external sphincter during rectal wall distension – the external anal inflation reflex – was observed in the patients with bilateral nerve sacrifice, indicating that this reflex is mediated below the S 2 level

Unilateral sacral denervation did not imply any significant impairment of anorectal function There was, however, a loss of sensibility on the denervated side, although this was of no significance for recognizing the quality of the rectal contents when they passed the anal canal The sense of rectal distension seemed normal as also did the reflex pattern of the internal anal sphincter The spontaneous activity of the external anal sphincter was of good quality bilaterally, but in some of the electromyograms a slight difference of activity between intact and denervated sides could be observed On brisk voluntary contraction there was an essentially normal increase of myoelectric activity bilaterally and this increased activity could be maintained on prolonged voluntary contraction as may be expected in normal subjects (Kadefors and Petersén 1970). This strongly suggests an overlap distribution of motor fibres from the right and left pudendal nerves and proves the sufficiency of only unilateral innervation of the external anal sphincter The investigations of Sherrington (1892) and Bishop (1959), who in animals produced contraction of the entire anal circumference with unilateral pudendal nerve stimulation, were thus confirmed

Several different aspects of anorectal function were studied. The significance of any of these factors per se for continence or defecation, however, can not be evaluated

Even though the internal anal sphincter had a normal reflex pattern in all patients the power of this sphincter cannot be judged It might well be that, at least in the patients with bilateral loss of sacral nerves, it had a weaker tone than ordinarily but still had the capacity to relax All other factors studied were negatively affected in this group of patients In spite of this heavily impaired anorectal function the patients managed astonishingly well with the help of diapers, constipating diet and regular bowel care

BIOMECHANICAL STUDY OF PELVIC STRENGTH (IV)

MATERIAL

Fifteen cadaver pelvises were studied They consisted of the pelvic ring with the fifth lumbar vertebra and were roughly cleaned from soft tissues except for the ligaments which were left intact. The specimens were kept in deep freeze and allowed to thaw at room temperature in moist wrappings 12 - 24 hours before testing The pelvises were divided into three groups with five specimens in each In the first group no resection was made *In the second group* sacroiliac resection was performed according to alternative A (see below) and in the third according to alternative B (see below) The specimens originated from patients who had died of diseases that did not directly engage the skeleton Cardiovascular diseases dominated the causes of death The age distribution was fairly wide, 29 85 years, but the age compositions of the different groups [illegible] similar *Two cases of uraemia were included (unresected group and group* [illegible]

[illegible]

from the medical records. A major difference in this respect between the different groups was, however, not likely

Resection A

The resection is illustrated in Figure 2, darkest fields.

Anteriorly, the resection comprised the whole of the sacrum except for the first segment Thus, the resection line ran between the bodies of S 1 and S 2 and through the *anterior opening of the first sacral holes. Posteriorly the resection also comprised parts of the first sacral segment, including the posterior opening of the first sacral holes* and the entire posterior wall of the sacral canal. From each iliac bone a *posterior part,* adjacent to the resected portion of the sacrum, was included. In this *manner,* about one-third of the sacroiliac joint with corresponding ligaments was removed on both sides.

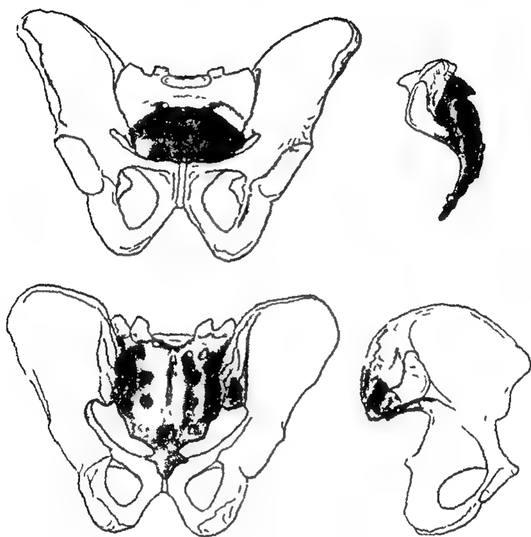

Fig. 2. Schematic drawing of resections performed in the biomechanical study on pelvic strength (IV).
Resection A. Darkest fields.
Resection B. Less dark fields also included.

Resection B

The resection is illustrated in Figure 2, less dark fields also included.

Anteriorly, the first sacral segment was divided about one centimetre below the promontory and the resection line ran superior to the first sacral holes. Posteriorly, the body of S 1 was divided only a few millimetres from the lumbosacral disc. A considerably larger part of each iliac bone than in Resection A was included so that only about half the sacroiliac joint with corresponding ligaments remained on each side.

METHOD AND CALCULATIONS

The ischial tuberosities and the inferior pubic rami of the pelvises were fixed in epoxy resin (Plastic Padding®) in a metal box in a position corresponding to upright standing (Boyd et al 1958) The specimens were loaded on the L 5 vertebra in a standard material testing machine (Alwetron Model T-2000), with a deformation speed of 5 mm/min. A strain gauge load cell transducer of 9810 N (1000 kp) with an accuracy of ± 1 % was used The load and the time were registered on an x-y-recorder over a measuring bridge and an amplifier The specimens were x rayed before and after testing.

To make it possible to judge the clinical significance of the experimental data the hypothetical loads in upright standing were calculated according to Nachemson and Elfstrom (1970), who have shown that the load on lumbar discs in upright standing may be calculated with the formula $P = 6 + 2.2\ W$, where W is the part of the body weight exerting load upon the disc This has been estimated by Ruff (1950), who found that approximately 60 per cent of the body weight lies above L 5

Prior to failure testing two specimens in each group were loaded one to three times up to approximately twice the estimated normal load in upright standing to find out whether any permanent tissue damage occurred at these loads Eventually all specimens were subjected to ultimate compressive loads

RESULTS

The preliminary tests with loading to approximately twice the estimated normal load in upright standing did not show any significant residual deformation

In the test to failure the mean ultimate compressive load in the group of unresected pelvises was 4856 N (standard deviation 824 N) The specimens resected according to A had a mean ultimate compressive load of 3286 N (standard deviation 1971 N) and those according to B 2484 N (standard deviation 1500 N)

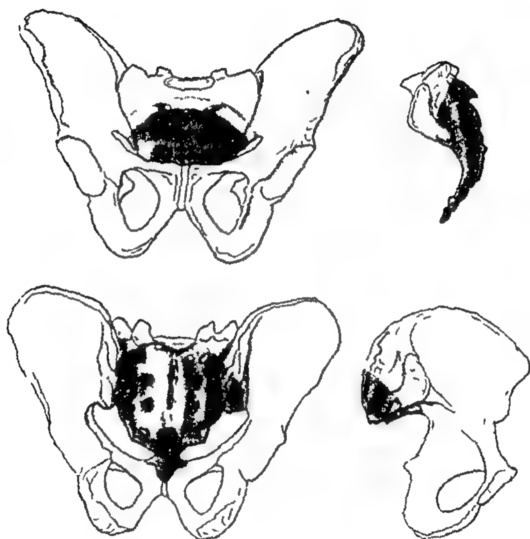

Fig. 2. Schematic drawing of resections performed in the biomechanical study on pelvic strength (IV).
Resection A Darkest fields.
Resection B Less dark fields also included.

strength was 4 - 8 times the calculated load in upright standing in the unresected group, 1.5 - 5 times after resection between S 1 and S 2, and about twice the calculated load after resection through S 1

From this study it seems safe with regard to residual strength of the pelvic ring to allow patients to stand and walk with full weight bearing at an early stage postoperatively after submaximal resection of the sacrum including adjacent iliac bone

All specimens fractured through the lateral parts of the sacrum relatively close to the sacroiliac joints, first on one side and then on the other The fracture localization was difficult to observe in the specimens after deloading when the sacrum returned almost to its original position due to the elasticity of the obviously uninjured sacroiliac ligaments If the deformation was allowed to continue well past the point of failure the injuries became more obvious and in resected specimens the S 1 vertebra or its remains eventually split Permanent dislocation of the sacroiliac joints did not occur in any specimen

DISCUSSION

The small number of specimens makes statistical evaluations unwarrented Tendencies can, however, be recognized It cannot be excluded that biological and other factors had influenced the specimens in a negative direction to weaken their strength. This would, however, be no disadvantage in this investigation as the safety margin concerning pelvic strength after major sacral resection would then in reality be greater than is shown by the study

A slow deformation speed (5 mm/min) was chosen mainly to make it possible to follow the deformation and terminal failure of the specimens visually Resistance to loading is lower when testing with low speeds than with high speeds (McElhaney 1966) Thus, the low testing speed might also have contributed to the registered ultimate compressive load values being minimum values

The sacroiliac junction is very strong Thus, the failure occurred in the lateral parts of the sacrum in unresected as well as resected specimens and the deformation curves also indicated a very low degree of permanent deformation of the soft tissues.

In this limited material the weakening of the sacroiliac region after resection according to A was approximately 30 per cent and after resection according to B approximately 50 per cent, as calculated from the mean values Information on the normal load in vivo on the pelvic ring is needed to evaluate our results and to judge whether the resections leave sufficient residual strength in the pelvic ring to allow early postoperative weight bearing. It should be borne in mind that the load at a certain vertebral level because of muscular activity, is greater than the weight of the overlying part of the body Nachemson and Elfström (1970) have shown that the load varies depending on posture, movements, etc ordinary slow walking increases the load by about 15 per cent, jumping on the floor and coughing by about 40 per cent, straining with erect posture by about 50 per cent and straining when seated by 5 35 per cent In the cases in which information on the body weight was available (11/15) a good margin was found between the calculated load in upright standing and the load at failure Thus, the test

Anorectal function was impaired when only the first and second sacral nerves had been spared. (*No patient with preservation of the third sacral nerves was studied.*) Soiling occurred and the sensation of rectal distension was defect as also was the sensibility of the anal canal. The internal anal sphincter displayed the normal reflex pattern even when only the first sacral nerves had been spared. There was weak spontaneous and voluntary myoelectric activity in the external anal sphincter when *only the first and* second sacral nerves were intact and no activity at all, *except for denervation potentials, when only the first* sacral nerves had been preserved.

In patients with unilateral loss of sacral nerves the *micturition reflex* was present even in *those with total unilateral sacral denervation* The bladder mucosa was anæsthetic *on the denervated side but the presence* of pain and thermal sensibility was demonstrated on the intact side

Sexual function was subjectively *unimpaired in patients with total unilateral sacral denervation In one patient* the normal clonic contractions of the striated urethral and anal sphincters during ejaculation were recorded electromyographically, although the contractions of the two sphincters alternated for some reason. The penis or labiae were unilaterally anæsthetic when the lower four or all sacral nerves had been sacrificed.

Anorectal function was subjectively unimpaired One sided sacral denervation implied deficient sensibility of the anal canal unilaterally but no disturbance of sphincter function

The **BIOMECHANICAL STUDY** was performed as vertical loading tests on the L 5 vertebra of 15 pelvic specimens divided into three groups, one with no resection, one with resection of the sacrum between the first and second segments and one with re*section through the first segment approximately 1 cm below the promontory* The resections also comprised substantial parts of the adjacent iliac bones. As calculated by mean values the approximate weakening of the pelvic ring by resection between S 1 and S 2 was 30 per cent and by resection through S 1 50 per cent To make it possible to judge the clinical significance of the experimental data the hypothetical loads in up*right standing were calculated according to Nachemson and* Elfstrom (1970). There appeared to be a reasonable safety margin between the calculated *loads and the loads* at failure This margin was about 4 - 8 times the calculated load in upright standing in the unresected group, 1 5 - 5 times after resection between S 1 and S 2, and about twice the calculated load after resection through S 1.

IN CONCLUSION, it seems necessary to spare at least one and perhaps both third sacral nerves in order to preserve normal bladder and anorectal function. The patients with bilateral loss of the lower three or four sacral nerves seemed, *however, in spite of* the loss of normal bladder and bowel *control to manage astonishingly* well with the

SUMMARY AND CONCLUSIONS

The purpose of this work was to study the clinical effects of major resection of the sacrum, with well-defined sacrifice of sacral nerves, concerning urogenital and anorectal function. Moreover, an answer was sought to the question what residual strength and safety margin are retained in the pelvic ring after major amputation of the sacrum.

The **CLINICAL STUDIES** were performed in altogether 10 patients in whom sacral nerves had been sacrificed during surgical procedures for radical removal of tumours Six patients had bilateral loss of sacral nerves (5 took part in the urogenital and 3 in the anorectal studies), and 4 had unilateral loss of sacral nerves (all took part in both the urogenital and anorectal studies)

Urinary function was studied by history, clinical evaluation, cystometry and cysto scopy including a test of vesical and urethral sensibility with different stimuli *Sexual function* was evaluated by history, and one patient with total unilateral sacral denervation was subjected to an electromyographic study of the external urethral and anal sphincters during ejaculation *Anorectal function* was studied by history, clinical evaluation, and simultaneous recordings of volume and pressure in the rectal ampulla, pressure changes in the internal anal sphincter region, and the myoelectric activity in the external anal sphincter

In patients with bilateral loss of sacral nerves there was no active *detrusor contraction* when only the first and second sacral nerves had been spared, indicating that segments below the S 2 level are essential for the micturition reflex This reflex was present when the third sacral nerves had been spared besides the first and second There was loss of bladder mucosal pain when the lower three sacral nerves had been sacrificed

Sexual function seemed unimpaired in women with preservation of only the first and second sacral nerves. A man with only the first sacral nerves spared had regular sexual intercourse but purely psychogenic erection, dripping ejaculations and a somewhat altered sensation of orgasm. The sensibility of the labiae and penis seemed to be mediated mainly in the second sacral nerves.

Anorectal function was impaired when only the first and second sacral nerves had been spared. (No patient with preservation of the third sacral nerves was studied.) Soiling occurred and the sensation of rectal distention was defect as also was the sensibility of the anal canal. The internal anal sphincter displayed the normal reflex pattern even when only the first sacral nerves had been spared. There was weak spontaneous and voluntary myoelectric activity in the external anal sphincter when only the first and second sacral nerves were intact and no activity at all, except for denervation potentials, when only the first sacral nerves had been preserved.

In patients with unilateral loss of sacral nerves the *micturition reflex* was present even in those with total unilateral sacral denervation. The bladder mucosa was anaesthetic on the denervated side but the presence of pain and thermal sensibility was demonstrated on the intact side.

Sexual function was subjectively unimpaired in patients with total unilateral sacral denervation. In one patient the normal clonic contractions of the striated urethral and anal sphincters during ejaculation were recorded electromyographically, although the contractions of the two sphincters alternated for some reason. The penis or labiae were unilaterally anaesthetic when the lower four or all sacral nerves had been sacrificed.

Anorectal function was subjectively unimpaired. One sided sacral denervation implied deficient sensibility of the anal canal unilaterally but no disturbance of sphincter function.

The **BIOMECHANICAL STUDY** was performed as vertical loading tests on the L 5 vertebra of 15 pelvic specimens divided into three groups, one with no resection, one with resection of the sacrum between the first and second segments and one with resection through the first segment approximately 1 cm below the promontory. The resections also comprised substantial parts of the adjacent iliac bones. As calculated by mean values the approximate weakening of the pelvic ring by resection between S 1 and S 2 was 30 per cent and by resection through S 1 50 per cent. To make it possible to judge the clinical significance of the experimental data the hypothetical loads in upright standing were calculated according to Nachemson and Elfstrom (1970). There appeared to be a reasonable safety margin between the calculated loads and the loads at failure. This margin was about 4 - 8 times the calculated load in upright standing in the unresected group, 1.5 - 5 times after resection between S 1 and S 2, and about twice the calculated load after resection through S 1.

IN CONCLUSION, it seems necessary to spare at least one and perhaps both third sacral nerves in order to preserve normal bladder and anorectal function. The patients with bilateral loss of the lower three or four sacral nerves seemed, however, in spite of the loss of normal bladder and bowel control to manage astonishingly well with the

help of diapers, incontinence bags, constipating diet and regular toilet visits. Sexual function in women is probably unimpaired by bilateral sacrifice of the three lower sacral nerves. In the male the preservation of only the first sacral nerves is, at least in occasional cases, compatible with sexual activity and intercourse, the stimuli being purely psychogenic. Total unilateral sacral denervation leads to no significant impairment of urogenital or anorectal function.

A submaximal sacral amputation, including adjacent iliac bone on both sides, seems not to imply any great risk for failure of the pelvic ring even if the patient is allowed to stand and walk with full weight bearing at an early stage postoperatively.

ACKNOWLEDGEMENTS

I wish to express my deep gratitude and admiration to Professor Bertil Stener, my esteemed chief and teacher. Without his skilful surgery this thesis would clearly never have been written. I am indebted to him for suggesting the projects, and for his constant support and constructive criticism throughout the studies.

My sincere thanks are also due to Professor Ingemar Petersén, Professor Torsten Sundin, and Associate Professor Jan Kewenter, who introduced me to their fields of research and who generously helped me in both word and deed and made available the facilities of their laboratories.

Special thanks are due to Roland Kadefors, Ph D., for invaluable work and discussions on the myoelectric tracings, Bertil Romanus, M D., for enlightening discussions on biomechanical problems, Lars Norlén, M D., for good co-operation in the urologic study.

It is also a pleasure to thank the following persons who have generously donated their special skills to this work:

Harriet Andersson	Barbro Johansson
Margareta Apelskog	Roland Johansson
Ann Bengtsson	Ole Roos
Barbro Ekmark	Birgitta Runze
Ian Goldie	Carl Sandell
Hans Hellström	Ingela Thorlin
Lars Irstam	Gunilla Widén

The English text has been revised by Mr John Gullner (frame story, II, III, IV) and Mr Stanley Pretorius (I).

Financial support has been received from Assar Gabrielsson's Fund for Clinical Cancer Research.

ACKNOWLEDGEMENTS

To do experimental work in addition to normal clinical daily duties is made possible only by the know-how, help and positive criticism made available by other workers, scientific or otherwise All who in this way have contributed to the completion of this thesis receive my heartfelt thanks

I wish to express my gratitude to Professor Dr Th J G van Rens for making available time and for his interest throughout this study The incentive to this investigation was given by Dr T J J H Slooff and I have greatly appreciated his dedicated support throughout the experiments and their analysis

In particular I have made grateful use of the actual help and advice of J R de Wijn Chem E (Department of Dental Materials), Dr F W Rhinelander (Professor of Orthopaedic Research, University of Arkansas, Little Rock, USA), R A M J Claessens Chem D (Department of Nuclear Medicine), J R Bakker, dispensing chemist and J Ellul, anesthesiologist

The original ideas and helpfulness of Messrs T J M Arnoldussen (Instrument Workshop), A J Peters, Th H M Arts, P H G Philipsen and G J T Grutters (Central Animal Laboratory) have been of much importance to me

Mrs Mieke H J Jacobs-Van den Hombergh and later Miss Diny H J Versleyen and Miss Gemma M J Bongers (Laboratory for Experimental Orthopaedics) prepared the specimens, and the autoradiograms were made with the technical assistance of N V M Rijntjes (Dispensary) Indispensable assistance was given by F E Schrijer (Instrumental Service) in fluorescence photomicrography The drawings were supplied by the department of Medical Illustration (head J J M de Bekker) I have greatly appreciated the efforts of the department of Medical Photography (head A T A Reynen), which supplied the photomicrographs and advice in the lay-out of this thesis The manuscript was typed with great care by Miss Irene A Keizer and Miss Petra M G Jansen

INTRODUCTION

The range of application of polymethylmethacrylate (PMMA) as acrylic bone cement in orthopaedic surgery is steadily increasing In particular, the use of acrylic cement has facilitated the solution of numerous problems in the fixation of artificial joints This has made it possible to expand the use of artificial joints and to give many patients with invalidating arthropathies a better life

According to Muller (1974b), some one-million patients have so far been treated by total hip replacement in Europe and the USA, and Bloch (1974) estimates that about a thousand total hip arthroplasties are now being performed every day all over the world!

Since the first total hip replacements with acrylic cement fixation were performed in the early Sixties, continued research has focused in particular on improvements in the mechanical characteristics of metal and plastic prosthetic components The orthopaedic surgeon is confronted with an unceasing flow of new types of prostheses, but acrylic bone cement has shown no fundamental modifications or improvements since it was first used by Charnley (1960) This is perhaps explained by the fact that the use of similar products in dentistry had been preceded by a long period of research

Although acrylic cement has generally lived up to its expectations, problems of fixation have not yet been fully solved Loosening of the prosthesis [redacted] being encountered in an increasing number of total hip *replacements, often years after its implantation and after an initial clinical* course which could only be described as favourable (Amstutz 1970, Wilson and Scales 1970, Wilson et al 1972, Patterson and Brown 1972, Salenius and Laurent 1973, van Rens 1973, Muller 1974a, 1974b, Deutman 1974, Dandy and Theodorou 1975) This late loosening, which totally invalidates a good result, is one of the greatest problems of total hip replacement today According to Muller (1974b), a 10-year follow-up on patients treated by total hip replacement can be expected to show that some 20 per cent will need a secondary operation in view of late complications, loosening being the most common This applies to patients operated on in highly specialized clinics by experienced surgeons

It is not easy to diagnose „loose prosthesis", and it may be several years before the situation is clinically evident Arthrography (Salvati et al 1971) and Strontium ^{87m} Sr bone scanning (Feith et al 1975) have proved to be

valuable diagnostic aids The late complication rates reported, even in larger series, should not be taken for granted It may well be that patients coming back with „obscure pain" and „diminished mobility and function" are really suffering from a loose prosthesis and in whom the diagnosis has been missed The proper diagnosis should have increased the total percentage of „late loosening" Moreover, in cases of late infection (always associated with loosening of a prosthesis component) it is rarely possible to establish whether the aseptic loosening or bacterial infection was the primary development

Possible causes of late loosening of normally used total hip prostheses include necrosis and resorption of the bony implant bed, insufficient cementing, excessive friction between the components of the prosthesis,

toxic influences exerted by the cement Partly due to interruption of the bone vascularization and partly due to direct damage, this results in the thin layer of necrosis of the bony implant bed described by Charnley (1970) and by Willert and Puls (1972) and Willert et al (1974b) As a result, the initial direct contact between bone and cement is partly lost. In the majority of cases adaptation of the implant by organization of the necrosis and regeneration of new bone is sufficient to produce what could be described as the *recipient's tolerance to the foreign body* In other cases however, in which the fixation of the components by the acrylic cement is lost, this necrosis might well be the principal cause of late loosening of the prosthesis, and it might also be the factor predisposing to late infection

The reasons why this necrosis develops has so far remained obscure The purpose of this study is to investigate the three factors generally accepted as causative, separately and in combination, in experiments using the rabbit femur These factors, of which the first two should be regarded as local side effects produced by the acrylic cement, are

1 the high maximal polymerization temperature of the acrylic cement setting in situ,

2 the local cytotoxic effect of the monomer,

3 interruption of the osseous vascularization by surgical manipulations required to prepare for implantation

Part of this study was presented as preliminary report at the 7th International Biomaterials Symposium held in Clemson, USA (Feith and Slooff 1975).

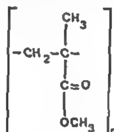
CHAPTER 1

ACRYLIC BONE CEMENT

1.1 *Introduction*

Polymethylmethacrylate (PMMA) was first used on a larger scale in orthopaedic surgery when the brothers Robert and Jean Judet introduced their Perspex or Plexiglas femoral head prosthesis in 1946. The initial results seemed promising (J. Judet et al. 1952) but in the longer run the acrylic prosthesis was found to be biologically and mechanically unsuitable for clinical use (Muller 1962, Anderson et al. 1964, Salvati and Wilson 1973). The Judet type metal prosthesis (La Chapelle) was likewise found to be unsatisfactory. The subsequently developed metal head neck prostheses (best known types: Austin Moore, Thompson, Eicher and Muller) were a marked improvement. However, not all biomechanical problems were yet solved. The fixation of these hemiarthroplasties remained the principal problem.

The interest in PMMA, but now as „bone cement", was revived when Charnley (1960) – advised in his choice of plastic by D. C. Smith – stabilized his first hemiarthroplasty of the hip with cold-curing PMMA. Shortly after, Charnley (1961) and McKee and Farrar (1966) each developed a total hip prosthesis which they anchored with acrylic cement. Since the early Seventies this bone cement has become an indispensable aid in orthopaedic surgery. The method of fixation which fills the space between the joint replacement and previously prepared bone defects with malleable plastic setting in situ, was revolutionary. It was therefore not until several years later that the concept of relying on the strength of the cement to support the prosthesis rather than having it rest on the bone, was generally accepted. Acrylic cement heralded the era of total joint replacements.



Excellent studies on PMMA have since been published in Dutch (Slooff 1970), English (1970) and German literature (Contzen et al. 1967, Oest et al. 1975*). To avoid repetition, the following sections will review only such aspects as are relevant to this study, and will discuss some recent developments.

* Published after completion of this manuscript.

1.2 *General characteristics*

1.2.1 Composition of the components

Polymethylmethacrylate is a plastic material composed of macromolecules. These in turn are made up of smaller units called monomers which, linked by chemical double bonds as a result of polymerization, form the links of the polymer chain. The ever-repeated unit in acrylic bone cement is the *methyl* ester of methacrylic acid (methylmethacrylate). Therefore the chemical name of the polymer is polymethylmethacrylate.

The material is prepared for implantation by mixing polymer powder with liquid monomer, which consists mainly of methylmethacrylate. The powder consists of tiny spherical particles of polymerized polymethylmethacrylate to which about 1 per cent benzoyl peroxide has been added (the initiator or catalyser).

The powder can in addition contain co polymers of methylmethacrylate with butyl methacrylate and styrene. It is also possible to add some radiopaque substance such as barium sulphate or zirconium dioxide, as well as antibiotics. The latter are released in a locally effective dose (Wahlig et al. 1972, Wahlig and Buchholz 1973, Koschmieder et al. 1973, 1975). The highest effective local concentration can be attained with gentamycin sulphate (Refobacin®, Garamycin®, usual dosage 500 mg/40 mg polymer powder) (Hessert and Ruckdeschel 1970, Buchholz and Gartmann 1972, Wahlig et al. 1972, Ruckdeschel et al. 1973, Marks et al. 1975).

After release from the cement of initially high microbiological concentrations of the antibiotic during the first three days, it is believed that a minimum inhibitory concentration of sufficient height can be maintained in the immediate vicinity of the implant up to 5 ▮ months after implantation (Wahlig et al. 1972, Wahlig and Buchholz 1973). According to Buchholz (1973), the antibiotic is still demonstrable even after 24 months. It is believed that addition of 100 mg streptomycin to the polymer powder ensures sufficiently high tuberculostatic concentrations in the tissue surrounding the implant (Knapmann 1974).

The liquid monomer is an inflammable, volatile, highly lipophilic fluid which has been demonstrated to be cytotoxic (Hulliger 1962, Willert et al. 1973c). A stabilizer or inhibitor (hydroquinone) has been added to it in order to prevent spontaneous polymerization, as activator has been

added a tertiary amine (dimethylparatoluidine), which releases from the benzoyl peroxide the free radicals required to open the double carbon bond in the monomer. No heat is required to initiate the reaction, hence the term cold-curing.

1.2.2 Handling and curing characteristics

The components form a system in which the relative quantities have been carefully determined by the manufacturer, and it is ill advised for the surgeon to alter the proportions indicated. The mixing of polymer powder and monomer liquid produces a soft paste which has the typical odour of the volatile monomer. In order to ensure maximum escape of the cytotoxic monomer prior to implantation, the substance is not introduced until after 1.5–4 minutes, when it has become putty like and there is just sufficient working time left to mould it at the appropriate site in the bone, whereupon the prosthesis is placed in position. It is of importance to ensure that the cement mass is still sufficiently malleable to enter even the smallest interstices in the bone. After waiting too long, the cement laminates and becomes mechanically weaker (Lee et al. 1973).

Kutzner et al. (1974a) determined by biological means that, after mixing acrylic cement (Palacos) at normal speed for 2.5 minutes, a total of 1.11 per cent monomer is released by evaporation up to 20 minutes after joining the components. Lee et al. (1973, 1975) found that monomer evaporation is promoted by thorough mixing; especially important was their finding that the amount of monomer released is directly proportional to the rate of stirring. Up to 14 per cent of the monomer could evaporate at a stirring rate of 260 beats per minute. The duration of mixing also played a role, but was less important. When mixing was discontinued, monomer evaporation was slight; this was confirmed by Roggatz (1974) and Debrunner and Wettstein (1975b). When mixing was resumed for 1 minute, ten times as much monomer was found to evaporate as when the cement was left alone. A similar effect was obtained by manual kneading for 1 minute (Lee et al. 1973, 1975). It is to be pointed out that manual kneading accelerates the setting process and slightly increases the maximal temperature peak due to an increase in ambient temperature (Haas et al. 1975).

Willert et al. (1973c) demonstrated in an experimental study that the cytotoxic effect of escaping monomer can be substantially reduced by having polymerization take place outside the body as long as possible. In a preliminary report, Debrunner and Wettstein (1975b) maintained that the principal monomer release occurs during the increase in temperature at polymerization. In their arrangement, no release was measurable any longer 2.3 minutes after setting.

The exothermic polymerization process needs some time to get properly started. With increasing heat release the phase in which the material is plastic ends and setting commences (fig. 1). When the cement is setting, the maximum curing temperature is reached at about the same time; this can locally be as high as about 100° C. The setting process still continues,

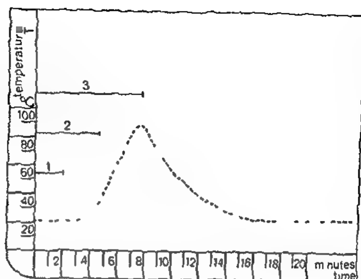


Fig 1 General shape of a *temperature-time curve* of acrylic cement, to elucidate the concepts of *terms mixing* time (1), working time (2) and setting time (3) these are *represented schematically* The duration indicated for (1) (2) and (3) is arbitrary

and it is only after several hours that the material attains its definitive degree of hardness (Haas et al 1975)

The working time of the various commercial bone cements varies considerably (Willert et al 1973c, de Wijn et al 1975, Debrunner and Wettstein 1975a) Other factors also play a role For example, when the powder liquid ratio diminishes (thereby increasing the amount of monomer), the setting time increases and the polymerization temperature attains a higher maximum (Meyer et al 1973)

Apart from the constituents, the speed of the reaction is also dependent on the volume of the cement mixture and on the ambient temperature The larger the cement mass, the longer the setting time Not only the room temperature but also that of mixingbowl, spatula, operation lamp, and the body temperatures of surgeon and patient must be taken into consideration (Meyer et al 1973) A higher ambient temperature shortens the working time and setting time, and vice versa By increasing the ambient temperature by 10° C, the polymerization process is accelerated by factor 1 5-2, and the working time is therefore halved (Debrunner and Wettstein 1975a) The maximum polymerization temperature attained also increases as the ambient temperature rises (Meyer et al 1973)

1 2 3 Polymerization heat

It has been reported that about 130 calories are released in the reaction per gramme of polymerizing monomer (Meyer et al 1973, Labitzke and

[illegible] that the total amount of heat produced in- [illegible]

[illegible]

process advances the reaction accelerates and more [illegible] per unit of time (Debrunner 1974). The maximally attainable polymeri- zation temperature is variously reported in literature as from 40 to 120° C (Wiltse et al. 1957; Slooff 1970, Debrunner 1974). The wide range of variation in laboratory results is explained by Slooff (1970) and by Hupfauer and Ulrtowski (1971) on the basis of insufficient standardization of

1. the measuring devices used;
2. the site of measurement in the cement;
3. the amount and consistency of the cement;
4. the monomer : polymer mixing ratio;
5. the surrounding material;
6. possible supply and release of heat;
7. measuring in vitro or in vivo.

Of course the maximum temperature of the cement surface measured in vivo is conclusive of any possible thermic tissue damage. In this context the German speaking authors attach great value to the critical limit of 56° C indicated by Lehmann (1959), at which body protein is alleged to coagulate, or to a limit of 70-72° C which Labitzke and Paulus (1974) hold to be the temperature at which bone collagen coagulates. These authors maintain that thermic necrosis need not be feared as long as one remains below this limit.

In in-vivo measurements in the bone cement interface in dogs, Homsy et al. (1972a) found temperatures of 70-90° C. Meyer et al. (1973) reported having found a maximum temperature of 70° C in the bone/acrylic interface during total hip arthroplasty in 10 different patients. In 10 patients treated by total hip arthroplasty, Biehl et al. (1974) measured in the trochanteric region a mean temperature of 46.6° C (range 42.6-51° C), and Labitzke and Paulus (1974) reported a mean temperature of 45.2° C (± 4° C) in 5 such patients. The last-mentioned authors found a mean maximum temperature of 50.4° C (± 7° C) at the interface of the prosthesis cup. Biehl et al. (1974) measured a mean temperature of 43.6° C (range 43-45.9° C) at the end of the femoral component of the prosthesis. Near the acrylic cement, and according to Debrunner (1974) from only 3 mm from the cement surface on, the maximum measurable temperature is much less high, not exceeding two fifths of the temperature of the cement surface. He thought it likely that in living tissue with an intact blood circulation the increase in temperature would be even less

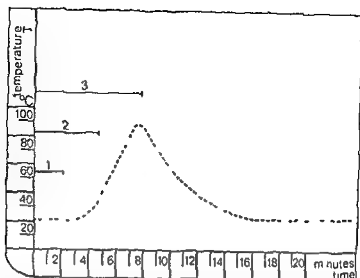

Fig 1 General shape of a temperature time curve of acrylic cement, *to elucidate* the concepts of terms mixing time (1), working time (2) and setting time (3) these are represented schematically The duration indicated for (1), (2) and (3) *is arbitrary*

and it is only after several hours that the material attains its definitive degree of hardness (Haas et al 1975)

The working time of the various commercial bone cements varies considerably (Willert et al 1973c, de Wijn et al 1975, Debrunner and Wettstein 1975a) Other factors also play a role For example, when the powder liquid ratio diminishes (thereby increasing the amount of monomer), the setting time increases and the polymerization temperature attains a higher maximum (Meyer et al 1973).

Apart from the constituents, the speed of the reaction is also dependent on the volume of the cement mixture and on the ambient temperature The larger the cement mass, the longer the setting time Not only the room temperature but also that of mixingbowl, spatula, operation lamp, and the body temperatures of surgeon and patient must be taken into consideration (Meyer et al 1973) A higher ambient temperature shortens the working time and setting time, and vice versa By increasing the ambient temperature by 10° C, the polymerization process is accelerated by factor 1 5-2, and the working time is therefore halved (Debrunner and Wettstein 1975a) The maximum polymerization temperature attained also increases as the ambient temperature rises (Meyer et al 1973)

1 2 3 Polymerization heat

It has been reported that about 130 calories are released in the reaction per gramme of polymerizing monomer (Meyer et al 1973, Labitzke and

2 *Apart from air* bubbles, acrylic cement setting in situ also loses strength due to admixture of blood and bone marrow The manner of application of the cement also influences its homo- [illegible] advantages of using a cement syringe,

[illegible]

is much less after introduction by means of a syringe [illegible] *digital introduction* (Slooff 1969, de Wijn et al 1974a)

3 Addition of a radiopaque substance and/or an antibiotic was reported not to interfere with the mechanical strength of the cement (Hessert 1971, Marks et al 1975) *This, however, was* refuted by Grunert and Ritter (1974), de Wijn et al (1975b) and Haas et al (1975) who demonstrated that these additions cause mechanical weakening of the cement due to loss of homogeneity *and increased water absorption*

4 Finally, there are indications that acrylic cement ages in situ *Water absorption alters the mechanical quality* (Bloch and Hastings 1972, Wagner and Bourgeois 1974)

Oest and Muller (1973) reported that test specimens of acrylic cement polymerized under pressure (dimensions 60 x 6 x 4 mm) and *when kept in Ringer solution at 20 C*, were found to be saturated with water after about 75 days Their weight had increased by 1 6 per cent, and they had therefore lost 20 per cent of their hardness An increase in temperature to 40 C resulted in another 20 per cent loss of hardness (Oest and Muller 1973) Jaffe et al (1974) however were unable to demonstrate any significant *deterioration of static properties or compression fatigue behaviour in* specimens of acrylic cement kept in bovine serum at 37 C for up to two years

As a result of the above mentioned factors the ultimate *compressive* and tensile strengths of Simplex P set in vivo are, according to Homsy (1973) and Lautenschlager et al (1974), an average only 20 35 per cent of those of *polymer obtained under factory conditions Acrylic cement* obtained at an operation was submitted to various strength determinations and found to be 50 per cent weaker than homogeneous test specimens (Oest and *Muller 1973, de Wijn et al 1974a, 1975b)*

de Wijn et al (1974a, 1975b) reported that in particular the greater porosity of PMMA setting in situ has an unfavourable effect on its mechanical properties It is difficult to answer the question whether weakening of the acrylic due to the above-mentioned factors is of essential significance for the success or failure of a joint replacement operation No exact figures are available on the minimum requirements which the mechanical properties of acrylic cement *should* meet (de Wijn et al 1975b)

Acrylic cement is not a glue, nor does it form any bond with living tissue at the molecular level *It is exclusively a filler*, which mechanically

than in the model set up. This hypothesis was confirmed by Biehl et al (1974) in comparative measurements at the interface between bone and cement during implantation of total hip and knee replacements. The knee prostheses were introduced under tourniquet ischaemia, and in these cases unmistakably higher temperatures were measured (on average 9.4° C higher).

Irrigation of bone surface and prosthesis has no significant effect on the maximum temperature (Ohnsorge and Goebbel 1970, Meyer et al 1973). It was found possible to reduce the maximum polymerization temperature by using prostheses cooled to 0° C (Ohnsorge and Goebbel 1970), by adding metal powder to the cement mixture (Homsy et al 1972), and by addition of co-polymers with longer chains (de Wijn 1974). The lastmentioned principle was used in the manufacture of the commercial acrylic cement Sulfix®, discussed in section 3.2. It is doubtful, however, whether these methods can sufficiently reduce the temperature to prevent thermic tissue damage. Moreover, the use of cooled prostheses has a number of disadvantages. For example, the marked auto-accelerating effect of the exothermic reaction, which gives this cement such attractive features for use in fixation, is inhibited (de Wijn 1974). Secondly, insufficient polymerization has an unfavourable effect on the mechanical properties of acrylic bone cement, and increases the percentage of monomer left in the cement (Puhl and Schultz 1971, Willert et al 1973c).

1.2.4 Mechanical properties

Studies with the scanning electron microscope (SEM) have shown that the structure of acrylic cement consists of an aggregate of previously polymerized polymer pearls, retained by cohesion to recently polymerized monomer. Polymerized PMMA, therefore, is a composite material in which no chemical bond has been established between polymer pellets and the monomer methylmethacrylate.

Many investigators have submitted the material to mechanical tests, demonstrating that it offers great resistance to compressive stress but less resistance to tensile and shear stresses (Wiltse et al 1957, Charnley 1970, Lautenschlager et al 1974, de Wijn et al 1975b, Haas et al 1975).

Several factors exert a negative influence on the mechanical properties:

1. Acrylic cement set in situ shows a certain degree of porosity due to inclusion of air bubbles during mixing and evaporation of monomer during the marked increase in temperature. The pores form a closed system and therefore do not communicate with each other. Porosity and mechanical hardness are inversely proportional (Debrunner 1975, de Wijn et al 1975b).

1 2 6 General toxicity of the monomer

The question of the general pharmacological effect of monomer on the [illegible] renewed attention since 1970 The reason [illegible]

[illegible] after introduction of acrylic cement and [illegible] the Anglo-American literature in particular presented from 1970 onwards a large number of case reports describing peroperative, sometimes irreversible cardiac arrest during hemiarthroplasty and total arthroplasty of the hip and total knee replacement. Series of such case reports recently compiled by Milne (1973), Dandy (1974) and Herndon et al (1974) can probably be supplemented with a by no means negligible number of unpublished cases Despite Charnley's denial (1970) and its corroboration by the anaesthetists of the Wrightington Hospital (Brittain and Ryan 1972), some authors maintained that these cardiovascular complications were to be largely ascribed to the cytotoxic, lipophilic (residual) monomer Later research has differentiated these views

Once PMMA is set, 2-5 per cent residual monomer remains in the cement and 1-2 per cent is gradually diffused to enter the tissues in minute amounts (Smith and Baines 1956, Kutzner et al 1974a, Haas et al 1975) According to Hullinger (1962) the initiator, activator and inhibitor are not cytotoxic in the small quantities normally used

A discussion of the local cellular and acute pharmacological cytotoxicity chiefly refers to the non polymerizing monomer which is released in the organism during the reactive process The possibly unfavourable effect of the so-called residual monomer (2-5 per cent) is negligible. The only thing really known about the local deleterious effect of non polymerizing monomer is that methylmethacrylate is cytotoxic The extent to which it may possibly contribute to tissue necrosis is unknown No research in this direction has so far been undertaken

According to Kutzner et al (1974a), methylmethacrylate ■ pharmacologically active in 1 11 per cent of the monomer added to the mixture (page 15) Monomer can be demonstrated in venous blood after intrafemoral application of acrylic cement in dogs (Homsy et al 1972a, McLaughlin et al 1973) and human subjects (Bloch et al 1970, Kim and Ritter 1972, Philips et al 1973, Pahuja et al 1974) The maximum concentration is reached during the rapid increase in polymerization temperature, but shortly afterwards it is no longer demonstrable in venous blood samples. Intravenously administered to test animals, the monomer was found to have three pharmacological effects

a. It increased the rate of respiration, and in increased doses led

stabilizes the cemented prosthesis Compressive, torsional and tensile forces are divided over a large bone surface area by the cement (Charnley 1970) Anchoring is further enhanced by intimate interlocking of the cement with surface irregularities

Stabilization of a prosthesis with acrylic cement partly depends on the number and the efficiency of interlockings of projections of the cement surface with surface irregularities of the surrounding bone tissue (Homsy 1973) The layer of fibrous connective tissue which forms at the interface (cf pages 25 to 30) allows minimal movements between bone and cement surface Charnley (1965, 1970) does not regard these as a disadvantage in fact he rather regards this fibrous interposition as a shock absorber which permits of elastic deformation between bone and cement – substances of different stiffness (the stiffness of PMMA is less than that of cortical bone but exceeds that of cancellous bone)

Mechanical theories become substantially more complex when the mechanical strength of the in-vivo „bond" between bone and acrylic cement is to be calculated, with the prosthesis in situ or otherwise Numerous variables are then to be taken into account, e g body weight, jolting stress, vascularization, mineralization and architecture of the bone as well as position, shape and mechanical properties of the prosthesis (Charnley 1965, 1970, Slooff 1970, Wilson and Scales 1970, Kolbel and Boenick 1972, Oest 1973, Kolbel et al 1973, Ritter et al 1973, Walker 1973, Jager et al 1974, Chen et al 1974) This general introduction does not *lend itself to a detailed discussion of this complex subject*

1 2 5 Volumetric changes

Theoretically predictable shrinkage (Contzen et al 1967, Haas et al 1975) of the product of polymerization was not corroborated by Charnley (1970) He measured an increase in volume by 3-5 per cent In subsequent studies Hupfauer (1973), Ohnsorge and Grotz (1974), Debrunner (1975), de Wijn et al (1975c) and Haas et al (1975) concluded that, after a slight initial increase in volume due to thermic expansion and foaming of the mixture, cooling of the mass to ambient temperature after curing causes a decrease in volume The percentages of decrease in volume reported by the above-mentioned authors vary from 1-4 volume per cent depending on the technique used In other words the cement shrinks during the period of rapid polymerization As the cement mass absorbs water, some of this volume loss can be regained in the long run (Oest and Muller 1973, Ohnsorge and Grotz 1974, de Wijn et al 1975c, Haas et al 1975)

Whether this slight decrease in volume during the final rapid phase of polymerization *might contribute to loosening of prostheses* is unknown In any case, this inevitable shrinkage cannot be expected to enhance fixation

1 2 6 General toxicity of the monomer

The question of the general pharmacological effect of monomer on the h [illegible] received renewed attention since *1970* The reason [illegible]

[illegible]

after introduction of acrylic cement and prosthesis into the [illegible] the Anglo-American literature in particular presented from 1970 onwards a large number of case reports describing peroperative, sometimes irreversible cardiac arrest during hemiarthroplasty and total arthroplasty of the hip and total knee replacement Series of such case reports recently compiled by Milne (1973), Dandy (1974) and Herndon et al (1974) can probably be supplemented with a by no means negligible number of unpublished cases Despite Charnley's denial (1970) and its corroboration by the anaesthetists of the Wrightington Hospital (Brittain and Ryan 1972), some authors maintained that these cardiovascular complications were to be largely ascribed to the cytotoxic, lipophilic (residual) monomer Later research has differentiated these views

Once PMMA is set, 2 5 per cent residual monomer remains in the cement and 1 2 per cent is gradually diffused to enter the tissues in minute amounts ([illegible] 1, Haas et al 1975) [illegible] rator and inhibitor are

A discussion of the local cellular and acute pharmacological cytotoxicity chiefly refers to the non polymerizing monomer which is released in the organism during the reactive process The possibly unfavourable effect of the so-called residual monomer (2 5 per cent) is negligible The only thing really known about the local deleterious effect of non polymerizing monomer is that methylmethacrylate is cytotoxic The extent to which it may possibly contribute to tissue necrosis is unknown No research in this direction has so far been undertaken

According to Kutzner et al (1974a), methylmethacrylate is pharmacologically active *in 1 11 per cent of the monomer added to the mixture* (page 15) Monomer can be demonstrated in venous blood after intrafemoral application of acrylic cement in dogs (Homsy et al 1972a, McLaughlin et al 1973) and human subjects (Bloch et al 1970, Kim and *Ritter 1972, Philips et al 1973*, Pahuja et al 1974) The maximum concentration is reached during the rapid increase in polymerization temperature but shortly afterwards it is no longer demonstrable in venous blood samples Intravenously administered to test animals, the monomer was found to have three pharmacological effects

a *It increased the rate of respiration, and in increased doses led*

to respiratory arrest by a direct inhibitory effect on the respiratory centre (McLaughlin et al 1973, Kutzner et al 1974b)

b It caused hypotension, probably as a result of decreased peripheral resistance in spite of an increase in cardiac output which as such might be caused by an increasing heart rate (Homsy et al 1972a, Peebles et al 1972, Holland et al 1973, McMaster et al 1974, Ellis and Mulvein 1974, Berman et al 1974),

c In large doses, it caused degeneration of pulmonary, hepatic and renal parenchyma (Contzen et al 1967, Homsy et al 1972a, McLaughlin et al 1973, Holland et al 1973)

The effects on respiration and blood pressure were both dependent on the monomer dose given

The hypotensive effect, moreover, can apparently be potentiated by a deficiency in circulating volume In addition, Berman et al (1974) demonstrated in hypovolaemic dogs a decrease in cardiac output which in their view was caused by venodilatation (monomer effect), resulting in venous pooling and diminished venous return It may also be mentioned that no ECG changes were found in test animals

In an analysis of possible local and systemic side effects of acrylic cement in human individuals, Convery et al (1975) were unable to demonstrate any untoward effects of PMMA on pulmonary, hepatic and renal function in patients after total hip replacement The majority showed mild transient hypotension, especially during application of acrylic cement and insertion of the endoprosthesis into the femoral shaft In the 10 patients whose cardiovascular function was recorded during the operation, the most constant change was a decrease in mixed venous oxygen saturation The most logical explanation in their view was a decreased cardiac output, probably caused primarily by peripheral venous pooling The authors (Convery et al 1975) apparently advanced their theory on the basis of Fick's principle, this, however, applies only in a steady state, and it is questionable whether a steady state is really maintained during introduction of acrylic cement and a prosthesis into the femoral shaft It is difficult to be certain what possible effect the monomer on its own can have So many other factors can influence the circulation

Modig et al (1973b) stated in a preliminary report that fat particles were found in blood samples from the pulmonary artery immediately after insertion of the femoral prosthesis in three out of four patients undergoing total hip arthroplasty With the aid of a Doppler flowmeter placed over the femoral vein, Herndon et al (1974) demonstrated fat embolism in patients during total hip replacement The largest number of „chirps" were heard during insertion of the femoral prosthesis Only an occasional chirp was heard during introduction of the cup, preparation

of f

from the femoral vein during the operation in a ... investigation they found no indications of systemic fat embolism. The ... of fat emboli could be unmistakably reduced by venting the med- ... on of

Although Herndon et al. (1974) did not ... these fat emboli can be assumed to have originated from the medullary cavity (chapter 2, page 45) in view of findings reported by Danckwardt-Lilliestrom et al (1970a, 1970b) and Kallos et al. (1974). The emboli enter the blood stream as a result of increased intramedullary pressure during ... particularly while the femoral prosthesis is being forced

(e g Philips et al 1973, Tronzo et al 1974) It is quite ... a causal relationship exists between these fat emboli and the above-mentioned acute peroperative cardiac arrests, for postmortems have repeatedly revealed massive pulmonary fat and bone marrow embolisms in these casualties (Milne 1973; Dandy 1974; Herndon et al. 1974) ... ternal heart massage had been applied; and

reticence, for these authors found fat and bone marrow emboli in the lungs at postmortems on 80 per cent of patients who had died after external

even though it is refuted by some authors (Brittain and Ryan 1972) Others (e g Fearn et al 1972) have confirmed it. However, comparison of anaesthetic techniques is almost impossible.

To summarize the above, it can be stated that it has not so far been demonstrated with certainty that the monomer, in the amount released during such procedures as total hip replacement, has any general pharmacological side effects on human patients Cardiovascular complications during hip replacement are more readily explained on the basis of systemic fat embolism A possible hypothesis is that of a combined effect or even an interaction between monomer and fat embolism, in the sense that the monomer is partly responsible for the development of fat emboli And the high polymerization temperature of the cement may also be of significance in this respect.

The only study referring to a combined effect has been one by Schlag et al (1973), who studied various cardiovascular functions in rabbits and dogs during intrafemoral

application of acrylic cement They advanced the hypothesis that circulatory decompensation results from an increased pulmonary

... the last suggestion was also made by Modig et al (1973a) The third factor, directly attributed to the monom...

... pulmonale

The possibility of interaction between monomer and fat embolism on the other hand, was suggested in studies by Dustmann et al (1972) and Koch et al (1972) They demonstrated histological features of extens...

... in only five out of ten animals Fat embolism was likewise only slight when a *different substance (Plasteline) was introduced* into the medullary cavity without suction drainage this fat embolism became more marked ...

... Of the ten animals in which the Lipostabil injection was combined with suction drainage of the medullary cavity none developed pulmonary fat embolism *The authors concluded* from these results that the monomer is of essential significance in the causation of fat embolism

In conclusion, it can be stated that even though no definite results have been reached, it can safely be admitted that application of acrylic cement, particularly in the femoral shaft, is known to cause a slight decrease in blood pressure and occasionally severe hypotension It seems therefore advisable to observe a number of rules The surgeon should ensure *optimal mixing as long as possible outside the organism and provide* adequate ventilation of the femoral shaft, the endoprosthesis should moreover be cased into its proper position Points of importance to the anaesthetist are to ensure adequate filling of the circulating volume before introduction of acrylic cement, and prevention of even slight hypoxia The possible contribution of the cytotoxic monomer to local tissue necrosis remains unknown

1 2 7 Allergy

So far there have been no indications of significant allergic complications caused by acrylic cement (and particularly by the monomer methylmethacrylate) in orthopaedic applications Sensitization to the monomer as reported in dermatological and dental literature (Slooff 1970, Charnley 1970), however, has been described in orthopaedic surgeons with contact

dermatitis (Pegum and Medhurst 1971, Blair Fries et al 1974) and in patients after total hip replacement with the aid of bone cement (Blair Fries et al 1974) The monomer seems to penetrate surgical gloves readily

Until the contrary is proved, the possibility that allergic reactions with serious consequences for the patient can be provoked by the cement components or additives must be taken into account (Bloch and Hastings 1972, Muller 1974b)

1 2 8 Carcinogenic effect

Partly in view of reports on sarcomatous degeneration after application of PMMA in test animals (Contzen et al 1967, Slooff 1970, Charnley

tion following surgical application of PMMA

Some 18 years after application of Lucite for extrapleural plombage of a tuberculous pulmonary process an extraskeletal chondrosarcoma was found in the supraclavicular fossa which proved to be directly related to the fibrous capsule enveloping the Lucite (Thompson and Entin 1969)

So far as could be established no malignant degeneration has ever been ascribed to any orthopaedic application of PMMA. However, after exposure of the human organism to recognized carcinogens it may be 20 35 years before a malignancy becomes manifest (Ott 1970 Lavorgna et al 1972) In view of the long latent period no definite conclusion can as yet be reached about the carcinogenic effect of acrylic cement on the human organism Discriminate use and prolonged follow ups particularly on younger patients, are therefore imperative

1 3 *Histopathological reactions*

1 3 1 Introduction

In descriptions given in the past of the effect of PMMA on living tissue, distinction must be made between tissue changes occurring in reaction to

a polymerized PMMA,
b PMMA setting in situ

All authors quoted by Contzen et al (1967), Slooff (1970) and Charnley (1970) regard polymerized acrylic cement as a biocompatible material The principal reaction mentioned is the development of a connective tissue membrane at the interface between PMMA and living tissue

When this material is exposed to stress, signs of chronic inflammation are seen in the connective tissue layer, with reactive necrosis and increased remodelling in adjacent bone tissue These reactions can increase due to disintegration of the PMMA and, together with mechanical imperfections, this ultimately led to rejection of the Judet type of Plexiglas prosthesis as mechanically and biologically unsuitable

The situation of PMMA setting in situ – the acrylic bone cement – is a different one It is in fact highly dubious whether this could be described as a biocompatible substance The possible untoward local side effects of the bone cement, most important among which is the high polymerization temperature and the cytotoxicity of the non-polymerizing monomer, become manifest in contact with the living organism The histopathological reactions which acrylic cement provokes in living human tissue can be divided into reactions in soft tissues and those in bone

1 3 2 Reactions in the soft tissues

After total hip arthroplasty, the movable parts of the artificial joints come to be surrounded by a new connective tissue capsule which replaces the capsule which is (usually) excised during the operation The histopathology of this new capsule, removed in revision operations or postmortems, has been described by Cotta and Schulitz (1970), Semlitsch et al (1971), Willert (1973a), Willert and Semlitsch (1973b, 1974a), Beneke et al (1973), Charosky et al (1973), Masshoff and Neuhaus-Vogel (1974), Evans et al (1974) and Brinkmann and Heilmann (1974)

Although the structure of the new capsule shows some resemblance to that of a normal joint capsule, yet an identical tissue structure is never attained The tissue structure shows changes and is much coarser because regenerative processes in the new connective tissue are accompanied by a tissue reaction to the presence of foreign bodies These foreign bodies are wear products of metal and plastic prosthesis components, and bone cement particles from the implant bed

According to Willert and Semlitsch (1973b, 1974a) acrylic cement particles are a major factor in the development of and the reactions in the new capsule They are held to contribute more to these than the wear products of the prosthesis components In the new capsule these foreign bodies produce a typical, partly granulomatous foreign-body reaction which varies with the degree of wear and other factors such as infection instability of the prosthesis and excessive amounts of acrylic cement The chronic foreign-body reaction maintained by constant addition of newly formed wear particles leads to progressive thickening and cicatrization of the new capsule, and over a long period of time this can produce

some loss of mobility in the artificial joint (Willert and Semlitsch 1973b, 1974a)

The granulation tissue tends to become necrotic, and necrotic material can be recovered in the form of cheese like debris from large pouches which have formed in the new capsule The wear particles are eliminated in minute amounts via the perivascular lymph interstices (Willert 1973a, Willert and Semlitsch 1973b, 1974a, Brinkmann and Heilmann 1974) If this elimination is insufficient or if the supply is too large, then this may lead in the long run to resorption of bone required for fixation of the cement, with consequent loosening of the prosthesis components (Willert and Semlitsch 1974a)

Evans et al (1974) maintain that hypersensitivity to metal wear particles can lead to several reactions which, via obliteration of supplying blood vessels, give rise to necrosis of the bony implant bed and ultimately cause loosening of the prosthesis

The development of this capsule should be carefully watched because it may give rise to pain, functional impairment, loosening of the prosthesis, and even possible sarcomatous degeneration (Willert and Semlitsch 1973b, 1974a, Charosky et al 1973) Although careful studies by the authors mentioned on page 26 have fortunately failed to demonstrate malignant degeneration following the use of acrylic cement in allo-arthroplasties, Willert and Semlitsch (1973b) and Charosky et al (1973) nevertheless stress the potential risks entailed by chronic progressive cicatrization on the basis of a foreign body reaction in this context

1 3 3 Reactions in bone

Charnley (1970) described the histopathological changes of bone in contact with acrylic cement with reference to postmortem findings obtained in 23 patients who had shown an uneventful clinical course after implantation of an artificial joint, which had remained stably fixed in the bone for many years (longest period reported 7 years) He observed that a thin layer of bone tissue (0 5 mm thick) in direct contact with the acrylic cement had become necrotic At the interface between bone and acrylic cement a connective tissue membrane had formed which contained giant cells but showed none of the typical signs of chronic inflammation From this connective tissue membrane a fibrocartilaginous tissue had developed by metaplasia induced by mechanical pressure In this tissue there were sometimes ossified areas, in contact with underlying bone tissue Dead bone had in part been replaced by new osteons which at some sites lay against the cement However, Charnley (1970) considered above all the fibrocartilaginous layer to be essential for the transmission of forces from cemented prosthesis to bony implant bed

On the basis of these observations and biomechanical theories (Charnley 1965), and supported by his good long term clinical and radiological results, Charnley (1970) described acrylic cement as a safe material which – although not yet ideal – meets all mechanical and biological requirements

Willert and Puls (1972) studied the histological reaction of bone to acrylic cement (Palacos) in 23 cases of total hip arthroplasty or hemiarthroplasty of the hip The material was obtained at *postmortem*, the operations having been performed 7 days to 5 years before this examination

In all patients whose operation dated back more than 10 weeks, the implant had borne weight and the clinical result had been satisfactory In alle cases fixation of cement to bone was macroscopically firm, and no mobility between cement and bone tissue was demonstrable Intimate interlocking of the cement in the interdigitations of the cancellous trabeculae was found in the metaphysis Along the compact bone of the diaphysis and along the acetabular floor the cement did exactly follow the bone surface, but at these sites the bone architecture happens to be less suitable for fixation as firm as that is possible in cancellous bone In these areas the cement consequently showed a much smoother surface Necrosis was found in a thin layer of bone (up to 3 mm) surrounding the cement, and large necrotic foci were found in the cancellous bone of the greater trochanter and in the medullary cavity of the femoral diaphysis distal to the point of the stem of the prosthesis Willert and Puls (1972) distinguished three phases in the tissue reactions to the implanted bone cement

a the initial phase, lasting up to 2-3 weeks after implantation,
b the phase of reparation, extending from 3 weeks to a year or longer,
c the phase of stabilization, which was completed after a maximum of two years

These three phases were best described in terms of microscopic features

In the *initial phase* fat cells and haemopoietic cells in the bone marrow degenerated There was lipophagia by polynuclear phagocytes which closely resembled foreign body cells The cancellous bone showed necrosis of cancellous trabeculae at sites of contact with the cement The extent of necrosis in the diaphyseal compact bone showed marked interindividual changes ranging from an area of 0 5 0 8 mm to one third of the inner surface of the cortex'

The phase of reparation was characterized by organization of the bone marrow necrosis to fibrosis in which avital bone marrow elements were still demonstrable after as long as one year The boundary with the vital bone marrow was demarcated by a hyperaemic marginal zone Beginning in areas where the bone marrow had been revitalized remodelling processes were taking place in the necrotic bone Osteogenesis took place by metaplasia of connective tissue in which woven bone was deposited,

areas, it was ... to the implant, with pr... in the cancellous bone, ... osteoclastic osteoporosis ... seen in elderly patients. The phase of reparation was ... 2 years after the operation. All necrotic tissue had been replaced by vital bone marrow and bone, and the bone cement was found surrounded everywhere by a thin layer of vital bone tissue.

giant cells. The bone marrow otherwise had a normal structure ... phase was characterized by further remodelling, with as conspicuous feature reorientation in the course of the bone trabeculae. While initially these had been arranged perpendicular to the bone cement, they were chiefly found to run more or less parallel to the cement surface in the phase of stabilization. Total bony enclosure of the acrylic was not observed anywhere in the material examined. By far the largest part of the interface consisted of bone marrow which showed a smooth or latticed meshwork structure. This bone marrow was separated from the cement by a connective tissue membrane in which, in the phase of stabilization also, haemorrhagic areas with fibrin deposits were seen.

less in evidence in the phase of stabilization. For the most part, the bone was not in direct contact with cement but separated from it by a thin zone of flat polynuclear cells. These cells were probably to be regarded as the equivalent of the giant cells in the cement/bone marrow interface. Wherever there was more space between bone and cement in the phase of stabilization, smooth or latticed meshwork marrow was found, separated from the cement by a connective tissue membrane.

The intensity of the changes described varied from case to case, and therefore the interval required for revitalization of necrosis and the healing process also varied. The impression was gained, moreover, that after early mobilization and weight-bearing the processes of degeneration and regeneration of bone were better balanced and led to less extensive osteoporosis.

The above described findings roughly correspond with those of Charnley, but they have been differently interpreted by Willert and Puls (1972) and Willert et al. (1974b). They maintained that the implant of prosthesis with cement owes its stability to anchoring in bone. In their view connective tissue membrane, regenerated bone marrow and soft tissues grown into the cement may mechanically function as a buffer which absorbs excessive forces impinging on the implant. They believe that the haemorrhages and exudates found in the connective tissue membrane corroborate this. In their opinion, the bone cannot be expected to interlock as intimately with

the cement during revitalization of the necrotic foci as at the time of insertion of the prosthesis According to Willert and Puls (1972), therefore, the anchoring in bone is never afterwards so firm as at the time when the cement is setting immediately after implantation!

Despite a favourable initial clinical course following a technically perfect operation, minimal movements between bone and implant can eventually occur due to diminution of the firmness of bony anchoring, as described by Charnley (1970), Willert and Puls (1972) and Willert et al (1974b) Should the demands made upon the implant exceed the strength of the cement/bone anchoring (and this is often unpredictable), instability of the implant inevitably results A series of microfractures in the interface upon continued stress can lead to loosening and even fracture of the cement (Homsy 1973, Willert et al 1974b) The tissue changes in the implant bed might very well lead to late loosening of the prosthesis It is therefore of importance to make an attempt at answering the ever-repeated question about the possible cause of this necrosis The three possibilities suggested are interference with the bone vascularization at operation, the high maximum polymerization temperature of the cement, and the cytotoxicity of the monomer

1 4 *Summary*

1 Acrylic bone cement as applied in joint-replacing operations has generally fulfilled expectations

2 Polymerization entails the development of a high temperature and the release of non-polymerizing cytotoxic monomer At a local level, these side effects might contribute to necrosis involving a thin layer of the bony implant bed We do not know whether this necrosis is caused by the untoward side effects of cement setting in the living organism or whether a vascular factor is (also) responsible

3 The general pharmacological toxicity of the monomer methylmetha crylate, in the amounts commonly used in acrylic cement, is not alarming

4 Sensitization and carcinogenic effects of acrylic cement used for orthopaedic purposes have so far been unknown, but cannot be excluded with certainty in the long run

5 Several factors exert a negative influence on the mechanical qualities of PMMA Shrinkage of acrylic cement could well be an unfavourable factor of some importance

6 Cement particles can contribute to an unmistakable extent to the reactive development of a greatly thickened new joint capsule

CHAPTER 2

THE VASCULARIZATION OF DIAPHYSEAL CORTICAL BONE AND THE REACTIONS TO DISTURBED MEDULLARY CIRCULATION

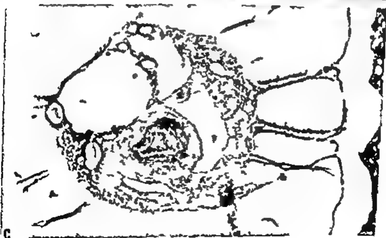
2 1 *Introduction*

The direct relationship between vascularization and osteogenesis has been recognized for centuries, but it is only in the past 25 years that attention and studies have focused on the anatomy of the osseous circulation on a microscopic level (Trueta 1968, Brookes 1971)

On the one hand this can be explained by the development of more advanced equipment to process bone and by the fact that perfected perfusion techniques have made it possible also to visualize microscopically small vessels On the other hand the more aggressive attitude adopted in the past few decades by orthopaedic surgery in dealing with congenital and acquired anomalies of the musculo-skeletal system may also have given impetus to the renewed interest

Our knowledge of the cortical circulation of diaphyseal bone in mammals, which for decades was based on the works of Langer (1876), Lexer et al (1904) and Johnson (1927), has been expanded in the years after World War II, mainly by the results of animal experiments It has been established that man and (test) animal, regardless of species, show the same basic patterns (Tilling 1958, Rhinelander 1962, 1972, Koekenberg 1963 Trueta 1968, Brookes 1971)

The arterial vascularization of a long bone has three sources the nutrient artery, the metaphyseal arteries (in combination with the epiphyseal vessels after closure of the growth plate), and the periosteal arterioles



2 2 *The vascularization of diaphyseal cortical bone*

2 2 1 Topographic anatomy of the vascularization of the diaphysis of the rabbit femur

The nutrient artery of the rabbit femur arises from the lateral circumflex femoral artery Over a distance of 2 cm it extends distally along the

lateral aspect of the iliopsoas tendon (Shim et al 1970) and enters the nutrient foramen This foramen extends obliquely to the knee and is localized on the medioposterior side of the femoral shaft, immediately distal to the lesser trochanter (Brookes & Harrison 1957) In the foramen the nutrient artery produces no branches Once in the medullary cavity after passing through the foramen, it divides into ascending and descending vessels whose branches supply the bone marrow and the cortex with blood (figure 2) In the cortex, arterioles which can be followed at best to a point halfway the cortex ultimately open up into the Haversian canals and Volkmann's canals, which contain one or two endothelium lined vessels the size of a capillary (Brookes 1971, Rhinelander 1974)

Among the *metaphyseal* arteries the artery of the trochanteric fossa, which arises from the medial circumflex femoral artery, merits some attention because, according to Brookes & Harrison (1957) and Brookes (1971), it could be a second afferent vessel for the diaphysis This artery enters through a foramen in the depth of the trochanteric fossa (Barone et al 1973), and divides into ascending branches which supply the greater and lesser trochanter as well as the femoral neck with blood The third trochanter (gluteal tuberosity of the femur) has no separate nutrient artery In addition, branches of the trochanteric anastomosis and the arterial ring at the base of the femoral neck enter the metaphysis through many foramina The distal femoral metaphysis is supplied by numerous metaphyseal arteries whose fairly thick branches penetrate the cortex through many foramina (Rogers & Gladstone 1950, Brookes & Harrison 1957, Brookes 1964)

The growing *epiphysis* has its own separate vascularization, and until completion of growth the growth plate constitutes a vascular barrier between the epiphyseal and the metaphyseal system (Trueta & Morgan 1960, Kockenberg 1963, Trueta & Cavadias 1964)

It is probably only at the capillary level that the medullary arteries anastomose with the metaphyseal vessels, after closure of the growth plate, anastomoses with the epiphyseal arteries probably do exist but have not been demonstrated with any certainty (Brookes 1971) According to Brookes (1964, 1971) this would imply that, generally speaking, under physiological conditions the diaphyseal, metaphyseal and epiphyseal systems supply only their own region with blood According to Shim et al (1970), the nutrient artery accounts for at least 70 per cent of the circulation of diaphysis and bone marrow, to which the other systems

contribute about 30 per cent Under normal conditions each of the regional systems accounts for at least two-thirds of the circulation *of its* primary supply region (Shim 1968) Trueta (1959, 1968) also refutes the notion that these systems consist of end-arteries

On the capillary level there is a direct communication between the *periosteal* network supplied by the periosteal arterioles, and the cortical capillaries At sites of muscle attachment (linea aspera), where the fibrous periosteum is firmly anchored to the bone, the intramuscular and the periosteal circulation merge The vascularization at these *sites* is *more* abundant than elsewhere in the periosteum (Brookes 1971, Rhinelander 1972, 1973)

A large number of *venous* sinusoids supplied by intracortical capillaries and medullary veins, drain into a central intramedullary canal which

extends throughout the length of the diaphysis and drains into the two venous metaphyseal systems This central venous sinus is many times as wide as the *nutrient* artery but has a much thinner wall According to de Marneffe (1951) and Tilling (1958), there are no valves in it In the diaphysis the nutrient vein is the sole ramification (Brookes & Harrison 1957, Morgan 1959, Brookes 1971)

2 2 2 Functional anatomy

A more profound insight into the significance of the above described systems can be gained when we consider the contribution of each system to the cortical vascularization of a long bone *in the functional sense* Two relevant theories merit a more detailed discussion

2 2 2 1 Singular circulation concept

According to Brookes (1971) and Rhinelander (1972) the medullary circulation, made up by the nutrient artery and also partly by the metaphyseal arteries through anastomoses *on a capillary level, is responsible* solely for the *afferent* cortical circulation They therefore maintain that, *under physiological conditions*, the direction of flow in the diaphyseal cortex is centrifugal

The periosteal network plays a subordinate role in the afferent circulation Possibly it contributes to the vascularization of a few superficial lamellae, and this is probably the case in immature cortical bone lined with a richly vascularized periosteum (Rhinelander 1974) Rhinelander (1971, 1973) attaches special significance to the periosteal arterioles in the vicinity of muscle attachments (linea aspera), which in this limited sector are believed to vascularize one-quarter to one third of the outer layers of compact bone The *afferent vascular system is* schematically represented in figure 3

Certainly in mature cortical bone the periosteal vessels are to be regarded as the final link in the *efferent* system The punctate haemorrhages which occur when periosteum is stripped off vital bone, indicate that blood leaves the cortex here Venous blood from the *intermediate system* made up by Volkmann s canals and Haversian canals, which constitutes the link between the afferent and the efferent system, ultimately drains through cortical venous canals into the extraosseous (periosteal) vascular network (Rhinelander 1972, 1974) The periosteal capillaries, which communicate with the cortical capillaries of the superficial cortical lamellae, should also be regarded as a *component part of* the efferent system It is mainly the medullary sinusoids and the central

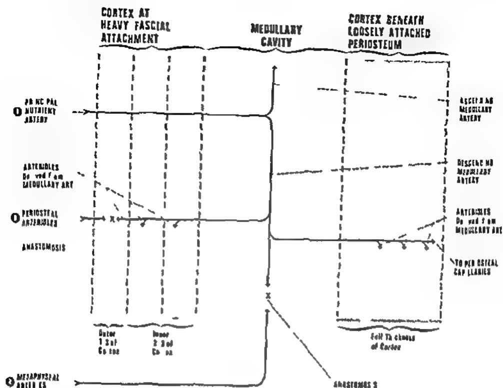

Fig 3 Rhinelander s diagram showing the afferent vascular system of a mature long bone and its distribution

Components 1, 2 and 3 constitute the total arterial blood supply to the diaphyseal cortex Arrows indicate direction of blood flow

contribute about 30 per cent Under normal conditions each of the regional systems accounts for at least two thirds of the circulation of its primary supply region (Shim 1968) Trueta (1959, 1968) also refutes the notion that these systems consist of end-arteries

On the capillary level there is a direct communication between the *periosteal* network supplied by the periosteal arterioles, and the cortical capillaries At sites of muscle attachment (linea aspera), where the fibrous periosteum is firmly anchored to the bone, the intramuscular and the periosteal circulation merge The vascularization at these sites is more abundant than elsewhere in the periosteum (Brookes 1971, Rhinelander 1972, 1973)

A large number of *venous* sinusoids supplied by intracortical capillaries and medullary veins, drain into a central intramedullary canal which

extraosseous arterioles penetrated the periosteal callus and vascularized osteoclastic removal of necrotic bone of the anterior and both lateral cortices This extraosseous circulation, however, was transient and was reduced to normal proportions as soon as the normal medullary system had sufficiently regenerated When physiological conditions are interfered with, therefore, e g by interventions which completely block the medullary blood flow, the direction of flow through cortex may be reversed by supply from the extraosseous system This new extraosseous circulation originates from soft tissues surrounding the fractured long bone and is a transient phenomenon (Rhinelander 1972) Gothman (1960a, 1960b) as well has shown that the extraosseous supply comes from the soft tissues It disappears after regeneration of the medullary circulation

2.2.2.2. Dual circulation concept

The concept outlined above has been refuted by Trueta & Cavadias (1955 1964), Trueta (1963, 1968) and Crock (1967), one of Trueta's co-workers They agree that the medullary system, to which the nutrient artery contributes some 70 per cent while the metaphyseal and epiphyseal arteries account for the remaining 30 per cent, is the most important system for the vascularization of the diaphyseal cortex But they restrict this to the inner two thirds of the compact bone, maintaining that here the centrifugal flow encounters a centripetal flow originating from the periosteal vessels which in their opinion supply the outer one third of the cortex They hold that the efferent venous flow from the cortex is mainly through the medullary venous system This view was supported by the experiments of Langer (1876) Johnson (1927), Foster et al (1951), Gothman (1960a) Larson et al (1961) and Kockenberg (1963)

They advanced their hypothesis on the basis of experiments with young and mature rabbit radii, in which the contribution made by each of the three sources of vascularization was determined by blocking the other two (Trueta & Cavadias 1964) For example, after blocking the metaphyseal vessels and severing the nutrient artery in young and mature animals they found that the outer one half to one third of the cortex remained vital Johnson s findings (1927) were identical After severance of the nutrient artery and suppression of the periosteal blood flow by stripping off the periosteum and placing a thin polythene sheath around the bone, one half to two-thirds of the inner cortex retained its vitality as long as the medullary circulation was taken over by anastomoses with the metaphyseal system If this did not happen (young animals), then total necrosis of the cortex resulted Similar results were reported after ligation of the nutrient artery and stripping of the periosteum in dog tibiae by Johnson (1927), in rabbits femurs by Foster et al (1951) and

venous sinus that are responsible for the drainage of bone marrow products These enter the medullary venous system by virtue of the permeability of the sinus endothelium, or by phagocytosis (Brookes 1971)

The above outlined concept of a centrifugal one-way afferent circulation of cortical diaphyseal bone, originally advanced by Brookes & Harrison (1957), has been corroborated by MacNab (1957, 1958), MacAuley (1958), Jackson & MacNab (1959), and Nelson et al (1960) And it has been elaborated and substantiated in excellent micro-angiographic studies by Rhinelander and his co-workers Suffice it here to present a summary of their principal results

Using fine granulated barium sulphate (Micropaque) as perfusion medium, the micro-angiograms were studied microscopically and stereoscopically, and correlated to the histology of sections originating from the same tissue slices Throughout the healing process of non dislocated radial and ulnar fractures in mature dogs the medullary circulation, which had remained intact, continued to dominate External callus was supplied by extraosseous circulation (Rhinelander et al 1962) In the case of dislocated fractures, however, with interruption of the medullary circulation, an increased periosteal or extraosseous circulation was found initially to be the primary source of vascularization for the forming callus (Rhinelander et al 1968a) A typical feature was the course of these vessels perpendicular to the cortex Three to six weeks after fracture infliction, the medullary circulation had regenerated and resumed its prominent place in the blood supply to the callus and the devitalized fracture fragments This process proved to be as much accelerated as reduction of the fracture had been more exact In radial osteotomies followed by stable plate fixation, reconstruction of medullary vessels was observed after only one week (Rhinelander 1968b, 1972) The significance of the temporarily increased extraosseous vascularization gradually diminished, and ultimately even the periosteal callus was supplied from the medullary circulation In the final stage of remodelling the normal pattern of vascularization returned, in which medullary vessels anastomosed with the periosteal vessels where they entered in the outer layers of the cortex at fascial attachments (Rhinelander 1968a, 1968b) Even after destruction of the medullary circulation by osteotomy of the tibia (Rhinelander 1965) or the ulna (Rhinelander et al 1967) in dogs, followed by insertion of a loose-fitting intramedullary rod, the medullary circulation proved to have enormous regenerative powers Insertion of a tight-fitting nail after reaming of the medullary cavity through a femoral osteotomy, resulted in temporary devascularization of the entire cortex, with the exception of a small posterior sector near the linea aspera (Rhinelander 1973) The medullary circulation regenerated gradually, and finally supplied the entire cortex with blood In the intermediate phase (8 weeks) of healing

extraosseous arterioles penetrated the periosteal callus and vascularized osteoclastic removal of necrotic bone of the anterior and *both lateral* cortices This extraosseous circulation, however, was *transient and* was reduced to normal proportions as soon as the normal medullary *system* had sufficiently regenerated When physiological conditions are interfered ... by interventions which completely block the medul- [illegible]

[illegible] originates from soft tissues surrounding the fractured long [illegible] transient phenomenon (Rhinelander 1972) Gothman (1960a, 1960b) as well has shown that the extraosseous supply comes from the soft tissues It disappears after regeneration of the medullary circulation

2222 Dual circulation concept

The concept outlined above has been refuted by Trueta & Cavadias (1955, 1964), Trueta (1963, 1968) and Crock (1967), one of Trueta's co-workers They agree that the medullary system, to which the nutrient artery contributes some 70 per cent while the metaphyseal and epiphyseal arteries account for the remaining 30 per cent, is the most important system *for the vascularization of the diaphyseal cortex But they restrict this to* the inner two-thirds of the compact bone, maintaining that here the centrifugal flow encounters a centripetal flow originating from the periosteal vessels, which in their opinion supply the outer one third of the cortex They hold that the efferent venous flow from the cortex is mainly through the medullary venous system This view was supported by the ex[illegible]
G[illegible]

and mature rabbit radii, in which the contribution made by each of the three sources of vascularization was determined by blocking the other two (Trueta & Cavadias 1964) For example, after blocking the metaphyseal vessels and severing the nutrient artery in young and mature animals, they found that the outer one-half to one third of the cortex *remained vital* Johnson's findings (1927) were identical After severance of the nutrient artery and suppression of the periosteal blood flow by stripping off the periosteum and placing a thin polythene sheath around the bone, one half to two-thirds of the inner cortex retained its vitality as long as the medullary circulation was taken over by anastomoses with the metaphyseal system If this did not happen (young animals), then total necrosis of the cortex resulted Similar results were reported after ligation *of the nutrient* artery and stripping of the periosteum in dog tibiae by Johnson (1927), in rabbits femurs by Foster et al (1951) and

in dog femurs by Larson et al (1961) The differences observed between young and mature animals would have to be explained on the basis of the insufficiency of the metaphyseo-medullary anastomoses in the young animals and the presence of the vascular barrier which the growth plate erects between epiphyseal and metaphyseal vessels (Trueta & Cavadias 1964)

Finally, if only the nutrient artery was left intact, most of the cortex was found to retain its vitality, and only the outer one-quarter showed necrosis This observation, too, confirmed Johnson's experiment (1927) Trueta found evidence substantiating the existence of a dual circulation in his observation (1963, 1968, p 167) that two or even three vessels extended in opposite direction in a single Haversian canal This finding, however, has never been corroborated by other investigators (Brookes 1971) except Brånemark (1959) The most prominent critics of the dual circulation concept have been Brookes and Rhinelander

2 2 2 3 Refutation of the dual circulation concept

According to Brookes (1971) the observation of cortical necrosis following stripping of the periosteum and its replacement with a plastic sheath is understandable as a consequence of venous obstruction Rhinelander (1972) also criticized this way of suppressing physiological functions The remarkable fact is that the opponents make use of the same weapon, i e both Brookes (1971, p 122) and Trueta (1968, p 168) find support for their arguments in a study by Nelson et al (1960) Referring to a vascular study of human tibiae, these authors stated „we agree with several recent studies (Brookes 1958, Brookes & Harrison 1957, MacNab 1957) that indicate that the periosteal vessels are of little significance in supplying arterial blood to the normal tibia"

More recent studies also seem to decide the issue in favour of Brookes and Rhinelander The dominant importance of the medullary circulation was likewise convincingly demonstrated by Danckwardt-Lilliestrom (1969), Danckwardt-Lilliestrom et al (1970a) and Olerud & Danckwardt-Lilliestrom (1971) Indian ink micro angiography and fluorochrome labelling were among the methods used in all the animal experiments next to be described

In the first study (Danckwardt-Lilliestrom 1969) the medullary circulation of growing and mature rabbits was destroyed by reaming, brushing or suction After these procedures the periosteal blood vessels initially proved capable of taking over nearly the entire cortical circulation As early as one week after the operation newly formed blood vessels had penetrated the medullary cavity Four weeks after the operation the reaction in the periosteal vessels had diminished, and the medullary

circulation had sufficiently regenerated to revascularize the inside of the cortex. After eight weeks there was no longer any difference in luminal [illegible]

[illegible] formed vessels which, in all growing rabbits and some 50 per cent of the mature animals, were identifiable as thick walled arteries, and in all animals as normal sinusoids. After reaming and brushing of the medullary cavity in mature dog femurs, the totally destroyed vascularization was found to have started regeneration within one week. Three weeks after the operation the revascularization of the medullary cavity was nearly complete, and one week later it was complete. The reactive periosteal vascularization was found to have returned to normal after six weeks.

In another experiment (Danckwardt Lilliestrom et al. 1970a), the medullary cavity of mature rabbit tibiae was reamed according to Kuntscher, whereupon a dome shaped transverse osteotomy was fixed under compression with a specially designed medullary nail. To promote rigid fixation of the osteotomy surfaces, the mid portion of the nail consisted of a massive metal cylinder with a length of 3.5 cm and a diameter which was 100 micra smaller than that of the burr last used. However, since the medullary cavity is not circular in cross section but triangular (proximal segment) or rectangular (distal segment), it was not quite occluded by the nail used. This procedure resulted in total destruction of the intramedullary circulation. At the level of the osteotomy, the periosteal vessels too showed discontinuity over a distance of 1 cm on either side of the cut surface.

The material was divided into two groups. In the first group, bone marrow was drained by suction through a separate aperture during reaming, whereupon an osteotomy was performed and the nail inserted. In the second group there was no suction of bone marrow during reaming. Marked differences in general reactions, severity of cortical necrosis, revascularization and fracture healing were observed between the two groups. An explanation of these differences will be offered on page 45.

The vascular reaction did not differ in principle from that in the first experiment. The first group (suction) showed quick restoration of the endosteal circulation: blood vessels were observed in the medullary cavity after one week, and the medullary circulation had largely regenerated after four weeks. This process took a considerably slower course in the second (non suction) group.

In a third experiment (Olerud & Danckwardt Lilliestrom 1971), dog tibiae were submitted to a double osteotomy with a Gigli saw, removing an annular diaphyseal segment, whereupon the cut surfaces were filed smooth. Next the avascular fragment was re inserted and fixed in situ by means of a plate mounted under compression. A study of the healing

in dog femurs by Larson et al (1961) The differences observed between young and mature animals would have to be explained on the basis of the insufficiency of the metaphyseo-medullary anastomoses in the young animals and the presence of the vascular barrier which the growth plate erects between epiphyseal and metaphyseal vessels (Trueta & Cavadias 1964)

Finally, if only the nutrient artery was left intact, most of the cortex was found to retain its vitality, and only the outer one-quarter showed necrosis This observation, too, confirmed Johnson's experiment (1927) Trueta found evidence substantiating the existence of a dual circulation in his observation (1963, 1968, p 167) that two or even three vessels extended in opposite direction in a single Haversian canal This finding, however, has never been corroborated by other investigators (Brookes 1971) except Brånemark (1959) The most prominent critics of the dual circulation concept have been Brookes and Rhinelander

2 2 2 3 *Refutation of the dual circulation concept*

According to Brookes (1971) the observation of cortical necrosis following stripping of the periosteum and its replacement with a plastic sheath is understandable as a consequence of venous obstruction Rhinelander (1972) also criticized this way of suppressing physiological functions The remarkable fact is that the opponents make use of the same weapon, i e both Brookes (1971, p 122) and Trueta (1968, p 168) find support for their arguments in a study by Nelson et al (1960) Referring to a vascular study of human tibiae, these authors stated „we agree with several recent studies (Brookes 1958, Brookes & Harrison 1957, MacNab 1957) that indicate that the periosteal vessels are of little significance in supplying arterial blood to the normal tibia"

More recent studies also seem to decide the issue in favour of Brookes and Rhinelander The dominant importance of the medullary circulation was likewise convincingly demonstrated by Danckwardt-Lillieström (1969), Danckwardt-Lillieström et al (1970a) and Olerud & Danckwardt-Lillieström (1971) Indian ink micro angiography and fluorochrome labelling were among the methods used in all the animal experiments next to be described

In the first study (Danckwardt-Lillieström 1969) the medullary circulation of growing and mature rabbits was destroyed by reaming, brushing or suction After these procedures the periosteal blood vessels initially proved capable of taking over nearly the entire cortical circulation As early as one week after the operation newly formed blood vessels had penetrated the medullary cavity Four weeks after the operation the reaction in the periosteal vessels had diminished, and the medullary

sometimes, a few avital remnants of bone marrow. *This blood clot is* organized by in-growth of markedly dilatated vessels, *and new bone marrow cells can be found* from the end of the first postoperative week on (e g Danckwardt-Lillieström 1969). Initially there is predominantly degradation of necrotic material with, as striking features, the presence of *macrophages* (Foster et al. 1951; Trueta & Cavadias 1955; Richany et al. 1965) and later of polynuclear giant cells (Bragdon et al. 1949, de Marneffe 1951; Trueta & Cavadias 1955, 1964; Brookes 1960). Trueta & Cavadias (1964) found these giant cells in young and mature rabbits as long as eight and six months, respectively, after blocking the medullary circulation (cf. page 37).

Dependent on the operative lesion, a fibrous network forms in the [illegible] 1960; Richany et al. 1965), this contains [illegible]

Foster et al. (1951) and Richany et al. [illegible] experiments, bone trabeculae were still found centrally in the medullary cavity six months after operation None of the investigators has described cartilage formation. Only Richany et al (1965) and Mital and Cohen (1966) have ventured to explain the appearance of new bone in the *medullary cavity following intramedullary operations* They suggested that pluripotent reticulum cells proliferate and then differentiate to mature bone marrow elements These include osteoblasts, which form trabecular bone during reorganization of the bone marrow. This bone formation in the medullary cavity was not observed in experiments in which, after extramedullary or intramedullary interruption of the medullary circulation, the medullary cavity was filled with foreign matter in the form of an intramedullary nail (Küntscher 1940, 1962; Trueta & Cavadias 1955, Guthman 19[illegible] Rhinelander [illegible] Nab 1958), [illegible] 1957, Slooff 1970, 1971, [illegible]

2 3 2 Cortical reactions

Within 24 hours of an intramedullary lesion or extraosseous blocking of the medullary circulation, *incipient necrosis of the endosteal cortex* can be observed in the form of *shrinkage* and hyperchromasia of cell nuclei (Foster et al 1951, Trueta & Cavadias 1964; Richany et al 1965) After a week the endosteal lining has become frayed or has

process revealed that four-fifths of the revascularization of this fragment was accounted for by the destroyed medullary vessels, which had regenerated after four weeks (shortest observation period) The presence of the plate on the medial aspect of the tibia exerted no influence on this process, because the pattern of revascularization on the lateral aspect of the tibia was identical

2 2 3 Conclusion

The evidence supplied by the above-mentioned authors through their highly original experiments lends further substance to the assumption that the concept advanced by Brookes (1971), with the modification introduced by Rhinelander (1972) for the vascularization of diaphyseal bone, is the more plausible of the two concepts discussed Under normal conditions the periosteal system is of subordinate importance for the cortical blood supply Under changed conditions, however, the extraosseous vessels prove to be of transitory importance After shaft fractures the medullary circulation remains dominant After complete interruption of the medullary circulation the centrifugal direction of flow may be reversed temporarily and the extraosseous system of healing bone may become the principal source of revascularization of the cortex

2 3 *Description of the reactions to disturbed medullary circulation*

The circulation in the medullary arterial system, which has been described above as the principal source of the vascularization of the diaphyseal cortex, can be partly or totally destroyed in various ways The ischaemia caused by intramedullary procedures has a number of typical consequences for the bone The reactions provoked in medullary cavity, cortex and periosteum are so characteristic and reproducible as to justify a joint discussion of all relevant animal experiments carried out in the past The intensity of these reactions largely depends on the extent of the lesion, the animal species involved, and the degree of maturity of the animals For a comprehensive review of the literature on intramedullary procedures we may refer to Danckwardt-Lillieström (1969, pp 17-22) and Danckwardt-Lillieström et al (1970a, pp 3-12)

2 3 1 Medullary reactions

Medullary devascularization leads to necrosis of the bone marrow After an intramedullary procedure, one initially finds a blood clot with,

sometimes, a few avital remnants of bone marrow This blood clot is organized by in-growth of markedly dilatated vessels, and new bone marrow cells can be found from the end of the first postoperative week on (e g Danckwardt Lilliestrom 1969) Initially there is predominantly degradation of necrotic material with, as striking features, the presence of macrophages (Foster et al 1951, Trueta & Cavadias 1955, Richany et al 1965) and later of polynuclear giant cells (Bragdon et al 1949, de Marneffe 1951, Trueta & Cavadias 1955, 1964, Brookes 1960) Trueta & Cavadias (1964) found these giant cells in young and mature rabbits as long as eight and six months, respectively, after blocking the medullary circulation (cf page 37)

Dependent on the operative lesion, a fibrous network forms in the medullary cavity (Brookes 1960, Richany et al 1965), this contains osteogenetic granulation tissue from which woven trabecular bone can be formed (Foster et al 1951, Brånemark et al 1964, Richany et al 1965, Danckwardt Lilliestrom 1969, Lindwer 1972) As bone marrow regeneration continues this new bone is resorbed (Danckwardt Lilliestrom 1969)

Foster et al (1951) and Richany et al (1965) reported that, in their experiments, bone trabeculae were still found centrally in the medullary cavity six months after operation None of the investigators has described cartilage formation Only Richany et al (1965) and Mital and Cohen (1966) have ventured to explain the appearance of new bone in the medullary cavity following intramedullary operations They suggested that pluripotent reticulum cells proliferate and then differentiate to mature bone marrow elements These include osteoblasts, which form trabecular bone during reorganization of the bone marrow This bone formation in the medullary cavity was not observed in experiments in which, after extramedullary or intramedullary interruption of the medullary circulation the medullary cavity was filled with foreign matter in the form of an intramedullary nail (Kuntscher 1940, 1962, Trueta & Cavadias 1955, Gothman 1960b Kockenberg 1963, Gustilo et al 1964, Anderson 1965, Rhinelander 1967, 1973, Danckwardt Lilliestrom et al 1970a), wax (McNab 1958) plaster of Paris (Slooff 1972) or acrylic cement (Wiltse et al 1957 Slooff 1970 1971, 1972, Lindwer 1972, 1975)

2 3 2 Cortical reactions

Within 24 hours of an intramedullary lesion or extraosseous blocking of the medullary circulation incipient *necrosis of the* endosteal cortex can be observed in the form of shrinkage and hyperchromasia of cell nuclei (Foster et al 1951, Trueta & Cavadias 1964, Richany et al 1965) After a week the endosteal lining has become frayed or has

process revealed that four-fifths of the revascularization of this fragment was accounted for by the destroyed medullary vessels, which had regenerated after four weeks (shortest observation period) The presence of the plate on the medial aspect of the tibia exerted no influence on this process, because the pattern of revascularization on the lateral aspect of the tibia was identical

2 2 3 Conclusion

The evidence supplied by the above-mentioned authors through their highly original experiments lends further substance to the assumption that the concept advanced by Brookes (1971), with the modification introduced by Rhinelander (1972) for the vascularization of diaphyseal bone, is the more plausible of the two concepts discussed Under normal conditions the periosteal system is of subordinate importance for the cortical blood supply Under changed conditions, however, the extraosseous vessels prove to be of transitory importance After shaft fractures the medullary circulation remains dominant After complete interruption of the medullary circulation the centrifugal direction of flow may be reversed temporarily and the extraosseous system of healing bone may become the principal source of revascularization of the cortex

2 3 *Description of the reactions to disturbed medullary circulation*

The circulation in the medullary arterial system, which has been described above as the principal source of the vascularization of the diaphyseal cortex, can be partly or totally destroyed in various ways The ischaemia caused by intramedullary procedures has a number of typical consequences for the bone The reactions provoked in medullary cavity, cortex and periosteum are so characteristic and reproducible as to justify a joint discussion of all relevant animal experiments carried out in the past The intensity of these reactions largely depends on the extent of the lesion, the animal species involved, and the degree of maturity of the animals For a comprehensive review of the literature on intramedullary procedures we may refer to Danckwardt-Lillieström (1969, pp 17-22) and Danckwardt-Lillieström et al (1970a, pp 3-12)

2 3 1 Medullary reactions

Medullary devascularization leads to necrosis of the bone marrow After an intramedullary procedure, one initially finds a blood clot with,

2.3.3 The periosteal reaction

The periosteal reaction of diaphyseal bone to intramedullary procedures is likewise highly typical. As described, the primary reaction is an increase in the number of extraosseous vessels. These are of greater-than-normal luminal width, take a meandering course and extend perpendicular to the cortex. After about two weeks this vascular proliferation is most pronounced (Danckwardt-Lillieström 1969), it diminishes after four weeks and is reduced to normal proportions after eight weeks if healing of the fracture or osteotomy can take place (Danckwardt-Lillieström 1969, Rhinelander 1973).

The osteogenic periosteal layer immediately shows marked cellular activity and reacts by the formation of new subperiosteal young bone. This layer of new bone may cover the entire surface of the diaphysis. Danckwardt-Lillieström (1969) distinguished two morphological types: a thinner layer of lamellar bone and a thicker layer of woven trabecular bone, with its trabeculae perpendicular to the cortex. Cartilage is found only at sites directly adjacent to an osteotomy or shaft fracture (i.e. never beneath intact periosteum). This formation of new bone usually attains its maximum after two to three weeks (Trueta & Cavadias 1955, Richany et al. 1965, Danckwardt-Lillieström 1969). In the course of subsequent weeks this young trabecular bone is gradually replaced by lamellar bone, and the demarcation between the old cortex and the new subperiosteal layer is effaced. At the same time, normalization of the extraosseous vascular reaction is observed.

Radiologically, the new bone initially has a cloudy appearance but eventually the structure becomes denser, and the entire cortex proves to have increased in diameter (Trueta & Cavadias 1954, Kuntscher 1962, Slooff 1970, Lindwer 1972, Rhinelander 1973). An exception is the experimental work of Gothman (1960b) who, after insertion of an intramedullary nail in mature rabbit tibiae, observed periosteal hyperplasia in only a few instances and subperiosteal bone apposition in none, in spite of marked extraosseous vascular proliferation. Periosteal new bone formation has been given a variety of names. Such designations as subperiosteal reaction (Richany et al. 1965, Danckwardt-Lillieström 1969), periosteal apposition (Lindwer 1972), provisional callus (Kuntscher 1940), external callus (Rhinelander 1973), new cortex (Anderson 1965, Danckwardt-Lillieström et al. 1970a) and secondary cortex (Slooff 1970), all refer to the same phenomenon.

The diameter of the new bone layer can be quite considerable. This, too, depends on the severity of the lesion and on the age and species of the test animal used. An interesting fact in this context is the similarity reported by Richany et al. (1965) and Kelly (1968a, 1968b) to the periosteal bone apposition seen in the long bones in pulmonary hyper-

disappeared, and one-third to two-thirds of the inner cortex has become necrotic (Trueta & Cavadias 1955, 1964, Richany et al 1965, Danckwardt-Lillieström 1969) In these areas the bone lacunae are empty After a while the Haversian canals and the bone lacunae dilatate, and after two weeks the partial cortical necrosis attains its maximum (Trueta & Cavadias 1964, Richany et al 1965, Danckwardt-Lillieström 1969)

As described in the first section of this chapter, extraosseous vessels react by a very marked proliferation and increase in luminal width, and such investigators as Danckwardt-Lillieström (1969) have demonstrated this within 24 hours Soon after, new blood vessels are observed, which penetrate the cortex from the periphery and eventually also from the medullary cavity With these new vessels, many „bone-forming cells" appear (Brookes 1971) Although one might expect predominance of degradation of necrotic tissue in the early stages, yet few osteoclasts are observed (e g Brookes 1960b)

Large resorption lacunae appear, first in the middle one-third of the cortex and then gradually also further down, where the necrosis is deepest In the inner cortex these lacunae come to occupy so much space that fragments of dead endosteal bone can be rejected as sequestra into the medullary cavity (Trueta & Cavadias 1955, 1964, Danckwardt Lillieström et al 1970a, Slooff 1970, Lindwer 1972) Large vascular spaces, sometimes filled with bone marrow, are left behind in the inner part of the cortex (Brookes 1960, Richany et al 1965, Slooff 1970 Rhinelander 1973) These spaces produce the radiological features of osteoporosis (Brookes 1960, Rhinelander 1973) Brookes (1960) refers to this process as „medullization", and Slooff (1970) speaks of „spongiozation" of the cortex

It should once again be clearly emphasized that the development of all these changes largely depends on the severity of ischaemia New endosteum begins to form after about six weeks (Richany et al 1965, Slooff 1970, Rhinelander 1973), and from this a new endosteal layer of lamellar bone is deposited At about the same time the process of resorption of dead cortical bone also attains its maximum intensity (Richany et al 1965, Danckwardt-Lillieström 1969) According to Danckwardt-Lillieström (1969, 1970), bone remodelling takes place by infiltration of large broom-shaped bundles of blood vessels, which anastomose with pre-existent intracortical vessels, and of vessels preceded by osteoclasts so called cutter heads (Schenk & Willenegger 1963) Even though the majority of investigators report complete revascularization after about eight weeks, necrotic areas can be encountered even after many months (Foster et al 1951, Trueta & Cavadias 1955, Gustilo et al 1964, Richany et al 1965, Slooff 1970) to years (Lindwer 1972) This applies in particular to older animals, in which the stimulus to recovery appears to become exhausted (Trueta 1968)

2.3.3 The periosteal reaction

The periosteal reaction of diaphyseal bone to intramedullary procedures is likewise highly typical. As described, the primary reaction is an increase in the number of extraosseous vessels. These are of greater-than-normal luminal width, take a meandering course and extend perpendicular to the cortex. After about two weeks this vascular proliferation is most pronounced (Danckwardt-Lillieström 1969), it diminishes after four weeks and is reduced to normal proportions after eight weeks if healing of the fracture or osteotomy can take place (Danckwardt-Lillieström 1969, Rhinelander 1973).

The osteogenic periosteal layer immediately shows marked cellular activity and reacts by the formation of new subperiosteal young bone. This layer of new bone may cover the entire surface of the diaphysis. Danckwardt-Lillieström (1969) distinguished two morphological types: a thinner layer of lamellar bone and a thicker layer of woven trabecular bone, with its trabeculae perpendicular to the cortex. Cartilage is found only at sites directly adjacent to an osteotomy or shaft fracture (i.e. never beneath intact periosteum). This formation of new bone usually attains its maximum after two to three weeks (Trueta & Cavadias 1955, Richany et al. 1965, Danckwardt-Lillieström 1969). In the course of subsequent weeks this young trabecular bone is gradually replaced by lamellar bone, and the demarcation between the old cortex and the new subperiosteal layer is effaced. At the same time, normalization of the extraosseous vascular reaction is observed.

Radiologically, the new bone initially has a cloudy appearance but eventually the structure becomes denser, and the entire cortex proves to have increased in diameter (Trueta & Cavadias 1954, Küntscher 1962, Slooff 1970, Lindwer 1972, Rhinelander 1973). An exception is the experimental work of Gothman (1960b) who, after insertion of an intramedullary nail in mature rabbit tibiae, observed periosteal hyperplasia in only a few instances and subperiosteal bone apposition in none, in spite of marked extraosseous vascular proliferation. Periosteal new bone formation has been given a variety of names. Such designations as subperiosteal reaction (Richany et al. 1965, Danckwardt-Lillieström 1969), periosteal apposition (Lindwer 1972), provisional callus (Küntscher 1940), external callus (Rhinelander 1973), new cortex (Anderson 1965, Danckwardt-Lillieström et al. 1970a) and secondary cortex (Slooff 1970) all refer to the same phenomenon.

The diameter of the new bone layer can be quite considerable. This, too, depends on the severity of the lesion and on the age and species of the test animal used. An interesting fact in this context is the similarity reported by Richany et al. (1965) and Kelly (1968a, 1968b) to the periosteal bone apposition seen in the long bones in pulmonary hyper-

disappeared, and one-third to two-thirds of the inner cortex has become necrotic (Trueta & Cavadias 1955, 1964, Richany et al 1965, Danckwardt-Lilliestrom 1969) In these areas the bone lacunae are empty After a while the Haversian canals and the bone lacunae dilatate, and after two weeks the partial cortical necrosis attains its maximum (Trueta & Cavadias 1964, Richany et al 1965, Danckwardt-Lilliestrom 1969)

As described in the first section of this chapter, extraosseous vessels react by a very marked proliferation and increase in luminal width, and such investigators as Danckwardt-Lilliestrom (1969) have demonstrated this within 24 hours Soon after, new blood vessels are observed, which penetrate the cortex from the periphery and eventually also from the medullary cavity With these new vessels, many „bone-forming cells" appear (Brookes 1971) Although one might expect predominance of degradation of necrotic tissue in the early stages, yet few osteoclasts are observed (e g Brookes 1960b)

Large resorption lacunae appear, first in the middle one-third of the cortex and then gradually also further down, where the necrosis is deepest In the inner cortex these lacunae come to occupy so much space that fragments of dead endosteal bone can be rejected as sequestra into the medullary cavity (Trueta & Cavadias 1955, 1964, Danckwardt-Lilliestrom et al 1970a, Slooff 1970, Lindwer 1972) Large vascular spaces, sometimes filled with bone marrow, are left behind in the inner part of the cortex (Brookes 1960, Richany et al 1965, Slooff 1970, Rhinelander 1973) These spaces produce the radiological features of osteoporosis (Brookes 1960, Rhinelander 1973) Brookes (1960) refers to this process as „medullization", and Slooff (1970) speaks of „spongiozation" of the cortex

It should once again be clearly emphasized that the development of all these changes largely depends on the severity of ischaemia New endosteum begins to form after about six weeks (Richany et al 1965, Slooff 1970, Rhinelander 1973), and from this a new endosteal layer of lamellar bone is deposited At about the same time the process of resorption of dead cortical bone also attains its maximum intensity (Richany et al 1965, Danckwardt-Lilliestrom 1969) According to Danckwardt-Lilliestrom (1969, 1970), bone remodelling takes place by infiltration of large broom-shaped bundles of blood vessels, which anastomose with pre-existent intracortical vessels, and of vessels preceded by osteoclasts so called cutter-heads (Schenk & Willenegger 1963) Even though the majority of investigators report complete revascularization after about eight weeks, necrotic areas can be encountered even after many months (Foster et al 1951, Trueta & Cavadias 1955, Gustilo et al 1964, Richany et al 1965, Slooff 1970) to years (Lindwer 1972) This applies in particular to older animals, in which the stimulus to recovery appears to become exhausted (Trueta 1968)

Although considerable research has been devoted to the physiology of the blood circulation in bone, and strong indications have been found that it is regulated via neural, hormonal and particularly metabolic routes, the exact mechanisms which control blood flow are still unknown (Shim 1968, Kelly 1968a, Sim & Kelly 1970)

2.3.4 Bone marrow embolism

Danckwardt Lilliestrom (1969) maintained that the ischaemia resulting from vascular interruption is alone insufficient to explain the variations in the extent of subperiosteal bone apposition and cortical necrosis which can be observed even in the same section There should be another factor which could cause avascularity He was the first to demonstrate that intracortical bone marrow embolisms are an important cause of the above described changes, and also that they can explain the occurrence of variations within the same bone after a medullary lesion As part of his experiment (cf page 38) he compared the percentage of avascular cortex with the amount of fat embolism demonstrated in intracortical vessels with the aid of Sudan 3 staining He found an unmistakable correlation He assumed that, due to an increase in intramedullary pressure resulting from the intervention, bone marrow was pressed into the Haversian canals and caused their obliteration The resulting intracortical block, he reasoned, contributed to the extent and intensity of the cortical necrosis and the reactive subperiosteal bone formation

Subperiosteally deposited bone marrow was also demonstrated When the bone marrow was removed by suction through a separate aperture in the distal metaphysis, thus at the same time reducing the intra medullary pressure, the vascular damage to the cortex was substantially less, and revascularization of the entire cortex was demonstrable four weeks after the operation (Danckwardt Lilliestrom et al 1970b)

The experience gained was confirmed in the second experiment (cf page 39) Both cortical necrosis and subperiosteal bone formation were substantially reduced after reducing the intramedullary pressure and removal of the bone marrow by suction It was also found that consolidation of the osteotomy was considerably quicker when the intracortical circulation was not blocked by fat embolism

The occurrence of fat embolism following intramedullary procedures is not confined to the osteotomized bone Olerud et al (1969) found massive fat emboli in the femoral vein after reaming a rabbit tibia. In the second experiment of Danckwardt Lilliestrom et al (1970a) described on page 39, the mortality due to pulmonary fat emboli was 11 per cent in the non-suction group, and 10 per cent of the animals showed unmistakable signs of systemic fat emboli, but survived

trophic osteoarthropathy Although vascular changes are probably the substrate of this symptom, the exact aetiological mechanism has so far remained obscure (Lipman & Massie 1964)

Several explanations have been suggested for the newly formed subperiosteal bone after intramedullary interventions

1 It has been ascribed to chemical or physical irritation caused by the material of the intramedullary nail (Kuntscher 1940, 1962) or to pressure exerted by the nail on the bone, or it has been regarded as a reaction to insufficient fixation of the bone fragments by the nail (L & J Bohler 1949)

2 Such investigators as Vanderhoeft et al (1963) reported periosteal bone apposition distal to an artificial arteriovenous fistula in growing dogs They were unable to offer an explanation

3 Richany et al (1965) contemplated the possibility of stasis and oedema, leading to local anoxia and prompting the formation of new bone

4 Zucman et al (1968) found bone marrow subperiosteally after reaming of rabbit tibiae and believed that this marrow, pressed through the cortical canals, could promote callus formation in the manner of an autograft

5 Kelly (1968b) produced periosteal tibial bone formation by placing a tourniquet around a thigh in growing dogs He observed increased pressure in the lateral saphenous vein and accelerated flow (clearance of ^{85}Sr) in the tibia He regarded increased pressure in veins and capillaries as the cause of the formation of a new layer of subperiosteal bone

6 Trueta & Cavadias (1955, 1964), who pointed out the prominent rule of the medullary circulation in the blood supply to the cortex, sought the primary cause in the ischaemia caused by intramedullary procedures which provokes proliferation of periosteal vessels with accompanying new bone formation Koekenberg (1963) also believed that the cause was to be found in interruption of the circulation Brookes (1971, p 242) likewise believed the ischaemia to be the causative factor, and he made special mention of the changed intravascular pressure relations Local periosteal hyperaemia could be followed by an increased cortical flow rate and changes in local oxygen and carbon dioxide pressures

As Sim & Kelly (1970) pointed out, the oxygen demand at a local metabolic level could be an important factor in blood flow regulation

Although considerable research has been devoted to the physiology of the blood circulation in bone, and strong indications have been found that it is regulated via neural, hormonal and particularly metabolic routes, the exact mechanisms which control blood flow are still unknown (Shim 1968, Kelly 1968a, Sim & Kelly 1970)

2 3 4 Bone marrow embolism

Danckwardt Lilliestrom (1969) maintained that the ischaemia resulting from vascular interruption is alone insufficient to explain the variations in the extent of subperiosteal bone apposition and cortical necrosis which can be observed even in the same section There should be another factor which could cause avascularity He was the first to demonstrate that intracortical bone marrow embolisms are an important cause of the above described changes, and also that they can explain the occurrence of variations within the same bone after a medullary lesion As part of his experiment (cf page 38) he compared the percentage of avascular cortex with the amount of fat embolism demonstrated in intracortical vessels with the aid of Sudan 3 staining He found an unmistakable correlation He assumed that, due to an increase in intramedullary pressure resulting from the intervention, bone marrow was pressed into the Haversian canals and caused their obliteration The resulting intracortical block, he reasoned, contributed to the extent and intensity of the cortical necrosis and the reactive subperiosteal bone formation

Subperiosteally deposited bone marrow was also demonstrated When the bone marrow was removed by suction through a separate aperture in the distal metaphysis, thus at the same time reducing the intramedullary pressure, the vascular damage to the cortex was substantially less, and revascularization of the entire cortex was demonstrable four weeks after the operation (Danckwardt Lilliestrom et al 1970b)

The experience gained was confirmed in the second experiment (cf page 39) Both cortical necrosis and subperiosteal bone formation were substantially reduced after reducing the intramedullary pressure and removal of the bone marrow by suction It was also found that consolidation of the osteotomy was considerably quicker when the intracortical circulation was not blocked by fat embolism

The occurrence of fat embolism following intramedullary procedures is not confined to the osteotomized bone Olerud et al (1969) found massive fat emboli in the femoral vein after reaming a rabbit tibia. In the second experiment of Danckwardt Lilliestrom et al (1970a) described on page 39, the mortality due to pulmonary fat emboli was 11 per cent in the non-suction group, and 10 per cent of the animals showed unmistakable signs of systemic fat emboli, but survived

trophic osteoarthropathy Although vascular changes are probably the substrate of this symptom, the exact aetiological mechanism has so far remained obscure (Lipman & Massie 1964)

Several explanations have been suggested for the newly formed subperiosteal bone after intramedullary interventions

1 It has been ascribed to chemical or physical irritation caused by the material of the intramedullary nail (Kuntscher 1940, 1962) or to pressure exerted by the nail on the bone, or it has been regarded as a reaction to insufficient fixation of the bone fragments by the nail (L & J Bohler 1949)

2 Such investigators as Vanderhoeft et al (1963) reported periosteal bone apposition distal to an artificial arteriovenous fistula in growing dogs They were unable to offer an explanation

3 Richany et al (1965) contemplated the possibility of stasis and oedema, leading to local anoxia and prompting the formation of new bone

4 Zucman et al (1968) found bone marrow subperiosteally after reaming of rabbit tibiae and believed that this marrow, pressed through the cortical canals, could promote callus formation in the manner of an autograft

5 Kelly (1968b) produced periosteal tibial bone formation by placing a tourniquet around a thigh in growing dogs He observed increased pressure in the lateral saphenous vein and accelerated flow (clearance of ^{85}Sr) in the tibia He regarded increased pressure in veins and capillaries as the cause of the formation of a new layer of subperiosteal bone

6 Trueta & Cavadias (1955, 1964), who pointed out the prominent rule of the medullary circulation in the blood supply to the cortex, sought the primary cause in the ischaemia caused by intramedullary procedures, which provokes proliferation of periosteal vessels with accompanying new bone formation Koekenberg (1963) also believed that the cause was to be found in interruption of the circulation Brookes (1971, p 242) likewise believed the ischaemia to be the causative factor, and he made special mention of the changed intravascular pressure relations Local periosteal hyperaemia could be followed by an increased cortical flow rate and changes in local oxygen and carbon dioxide pressures

As Sim & Kelly (1970) pointed out, the oxygen demand at a local metabolic level could be an important factor in blood flow regulation

and, depending on the severity of the ischaemia produced, this necrosis can involve almost the entire cortex The avascular bone marrow also becomes necrotic

During the repair phase the medullary circulation proves to have enormous regenerative powers, and after a while it can entirely resume its function in the cortical blood supply This concludes the importance of the temporary extraosseous vessels as a collateral system, and the rapid formation of young bone likewise subsides This subperiosteal bone layer matures and is partially incorporated in the old cortex. In the cortex, dead bone is resorbed through invasion of new vessels, and replaced by new bone, for instance, a newly formed endosteum deposits a layer of lamellar bone This process can take a very long time, and is associated with the formation of large vascular spaces which may contain bone marrow, and with sequestration of necrotic endosteal bone to the medullary cavity During the reorganization of the bone marrow after reaming, macrophages and giant cells may be strikingly numerous Also, scattered spicules of bone may form centrally in the medullary cavity, to be eventually resorbed

Finally, it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure

The possible correlation between high intramedullary pressure and pulmonary fat embolism has also forcefully come to the fore in a different context Postmortems on patients who had died of acute cardiac arrest during a total hip or knee arthroplasty or hemiarthroplasty of the hip in which bone cement was used, revealed massive fat and bone marrow embolism in the lungs (Milne 1973, Dandy 1974, Herndon et al 1974)

This was initially interpreted as a possible side effect of the acrylic cement used, and special importance was attached in this respect to the lipophilic monomer (page 21)

Recent animal experiments carried out by Kallos et al (1974b) have confirmed, however, that the occurence of pulmonary bone marrow emboli is a direct result of an increase in intramedullary pressure No effort was made to establish the extent to which acrylic cement constituents, too, may influence the occurrence of fat embolism (cf page 62)

2 4 *Summary*

Under physiological conditions the arterial afferent vascularization of the diaphyseal cortex of a long bone is dependent on the medullary circulation This is supplied by the nutrient artery (arteries), and in part by anastomoses with the metaphyseal arterial system The flow is centrifugal The periosteal vessels are thought to be of subordinate importance in this vascularization, only a small outer cortical sector near the sites of muscle attachment (linea aspera of femur) being supplied by periosteal vessels

Intramedullary procedures interfere with this pattern Depending on the severity of the lesion involved, the endosteal circulation is partly or totally interrupted, thus depriving the cortical bone of its principal source of blood supply Moreover, the cortical ischaemia is also in part determined by the occurrence of intracortical bone marrow emboli These are as much more numerous as the intramedullary pressure during the intervention is higher (Danckwardt-Lilliestrom and co-workers) The reaction pattern of, in succession, the diaphyseal cortical circulation, the periosteum, the cortex and the medullary cavity is characteristic and reproducible It is largely dependent, however, on the severity of the lesion, the increase in intramedullary pressure involved, the animal species used and the age of the animal

To some extent the extraosseous circulation of healing bone is capable of taking over the circulation in the diaphyseal cortex The afferent flow becomes temporarily centripetal Proliferation of the extraosseous vessels is accompanied by the formation of a subperiosteal layer of young bone over the entire cortical surface The inner cortical layers become necrotic

and, depending on the severity of the ischaemia produced, this necrosis can involve almost the entire cortex The avascular bone marrow also becomes necrotic

During the repair phase the medullary circulation proves to have enormous regenerative powers, and after a while it can entirely resume its function in the cortical blood supply This concludes the importance of the temporary extraosseous vessels as a collateral system, and the rapid formation of young bone likewise subsides This subperiosteal bone layer matures and is partially incorporated in the old cortex In the cortex, dead bone is resorbed through invasion of new vessels, and replaced by new bone, for instance, a newly formed endosteum deposits a layer of lamellar bone This process can take a very long time, and is associated with the formation of large vascular spaces which may contain bone marrow, and with sequestration of necrotic endosteal bone to the medullary cavity During the reorganization of the bone marrow after reaming, macrophages and giant cells may be strikingly numerous Also, scattered spicules of bone may form centrally in the medullary cavity, to be eventually resorbed

Finally, it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure

The possible correlation between high intramedullary pressure and pulmonary fat embolism has also forcefully come to the fore in a different context Postmortems on patients who had died of acute cardiac arrest during a total hip or knee arthroplasty or hemiarthroplasty of the hip in which bone cement was used, revealed massive fat and bone marrow embolism in the lungs (Milne 1973, Dandy 1974, Herndon et al 1974)

This was initially interpreted as a possible side effect of the acrylic cement used, and special importance was attached in this respect to the lipophilic monomer (page 21)

Recent animal experiments carried out by Kallos et al (1974b) have confirmed, however, that the occurence of pulmonary bone marrow emboli is a direct result of an increase in intramedullary pressure No effort was made to establish the extent to which acrylic cement constituents, too, may influence the occurrence of fat embolism (cf page 62)

2 4 *Summary*

Under physiological conditions the arterial afferent vascularization of the diaphyseal cortex of a long bone is dependent on the medullary circulation This is supplied by the nutrient artery (arteries), and in part by anastomoses with the metaphyseal arterial system The flow is centrifugal The periosteal vessels are thought to be of subordinate importance in this vascularization, only a small outer cortical sector near the sites of muscle attachment (linea aspera of femur) being supplied by periosteal vessels

Intramedullary procedures interfere with this pattern Depending on the severity of the lesion involved, the endosteal circulation is partly or totally interrupted, thus depriving the cortical bone of its principal source of blood supply Moreover, the cortical ischaemia is also in part determined by the occurrence of intracortical bone marrow emboli These are as much more numerous as the intramedullary pressure during the intervention is higher (Danckwardt Lilliestrom and co workers) The reaction pattern of, in succession, the diaphyseal cortical circulation, the periosteum, the cortex and the medullary cavity is characteristic and reproducible It is largely dependent, however, on the severity of the lesion, the increase in intramedullary pressure involved, the animal species used and the age of the animal

Finally, it has been found that an intramedullary procedure can lead to systemic fat or bone marrow embolism as a result of a local increase in pressure

CHAPTER 3

DESCRIPTION OF THE EXPERIMENT

3 1 *Objective, argumentation and design*

The objective of the investigation to be described was to establish, on the basis of animal experiments, which local side effects of acrylic cement cause the histological changes in cortical bone

In the analysis of these side effects of acrylic cement, they had to be distinguished from the reactions which occur in cortical bone after interruption of the medullary vascularization, as described in chapter 2

To begin with, the effect of interference with the medullary vascularization had to be studied in the model chosen for this study the rabbit femur Next, it had to be established which histological changes occur in cortical bone when acrylic cement is implanted in addition For this purpose the two principal local side effects – those of the high polymerization temperature and the cytotoxicity of the monomer – had to be separately compared with the tissue reactions caused by interruption of the medullary vascularization

For a separate study of the high temperature effect, we had to look for an acrylic cement which showed no or only a negligible rise in temperature at a constant monomer content The effect of this cement had then to be compared with the reactions caused in bone by commercial acrylic cement A simple „subtraction' would then give the tissue damage due to the effect of the high maximum polymerization temperature

For a separate study of the monomer effect, an acrylic cement had to be found which contained a monomer excess but showed no rise in temperature For this, too, we had to establish the extra effect in tissue damage besides the effect of interruption of the medullary vascularization The reactions thus obtained had then to be compared with those produced by cement with a low maximum polymerization temperature and a normal monomer content

A supplementary study had to be made of the additional deleterious effect of monomer leaking from set cement (so-called residual monomer 2-5 per cent which remains in cured PMMA, page 21) The results thus obtained had to be compared with those produced solely by interruption of the medullary vascularization

In this manner, it was argued, it would be possible to gain from the rabbit femur an impression of which reactions in diaphyseal cortical bone are caused by

1 interruption of the medullary vascularization,
2 cytotoxicity of an overdose of monomer,
3 cytotoxicity of a very small amount of monomer which leaks from a set cement mass,
4 high polymerization temperature of acrylic cement setting in situ

In order to separate these four effects, different cement types were used (section 3 2) The test animals used in this study (section 3 3) were divided into seven different groups (section 3 6) after the operation (section 3 4)

In order to study the changes in the vascularization of diaphyseal cortical bone, the lower limbs of the test animals were perfused with a fine granular barium sulphate suspension after sacrifice (section 3 7) Vascularization patterns were studied radiologically (section 3 8) and microangiographically (section 3 10)

The histopathological changes of cortical bone were studied after processing the femurs for histological (section 3 9), fluorescence microscopic (section 3 11) and autoradiographic (section 3 12) examination

3 2 *Cement types*

Three types of cement* were used in the experiment

a *commercial acrylic cement* (Palacos and Sulfix 6),
b. *a catalyst free , acrylic cement '* obtained from one of the commercial plastics (Palacos and Sulfix-6),
c a modified acrylic cement (Sulfix-6 with CMC gel)

3 2 1 Palacos and Sulfix 6

The properties of Palacos which has been used in Europe for many years can be presumed known The ratio polymer powder with radio-paque contrast medium monomer fluid is 2 1 The conventional packings contain about 40 g powder and 20 ml fluid

* Palacos® and Sulfix® were respectively supplied by *Kulzer & Co* GmbH 638 Bad Homburg v d H., Germany and Sulzer Bro Ltd, CH-840 Winterthur, Switzerland.

Sulfix-6 is a new commercial product described by the manufacturer as different from products marketed earlier (Palacos, CMW and Simplex-P) in that it has a number of improved properties It is somewhat more finely granular and has a longer working time (Debrunner and Wettstein 1975a), because 15 per cent of the fluid consists of the co polymer n-butylmethacrylate, there is an indication of a (not significantly) lower maximum polymerization temperature at the cement surface (Debrunner 1974), and its lower porosity (Semlitsch 1975) is believed to give it slightly better mechanical properties than the other commercial acrylic cements There are no differences in monomer release (Debrunner and Wettstein 1975b), tissue toxicity of the cured product (Semlitsch 1973) and volumetric changes during polymerization (Debrunner 1975) As in Palacos, zirconium dioxide has been added to the polymer powder as radiopaque contrast medium The ratio polymer powder monomer fluid is 5 2 Conventional packings contain 40 g powder and 16 ml fluid

3 2 2 Catalyst-free „acrylic cement"

As described in section 1 of chapter 1, polymerization occurs by virtue of the presence of an initiator in the powder and an activator in the fluid When the benzoyl peroxide (initiator) is washed out with methanol, no polymerization reaction occurs the end-product becomes neither warm nor hard One obtains a rubber-like substance which remains malleable for days but, exposed to air, sets after about a week due to evaporation of the monomer, this is accompanied by an unmistakable decrease in volume We had the disposal of polymer powder and monomer fluid without catalyst system Since no polymerization takes place in this „cement", an overdose of monomer remains in it (about 30 volume per cent) By eliminating the high polymerization temperature we could separately study the cytotoxic effect of this excess of monomer

3 2 3 Modified acrylic cement Sulfix-6 with CMC gel*

Next we looked for a cement which would enable us to eliminate the factor polymerization temperature Initially we succeeded in reducing the maximum polymerization temperature by adding water when mixing the cement Due to phase separation however, no homogeneous distribution of water and cement could be obtained Moreover, the mixture could not be used in the syringe By using a high-viscosity gel, J R de Wijn Chem E (Department of Dental Materials, Nijmegen University)

* Sulzer Bro Ltd, Winterthur, Switzerland patents pending

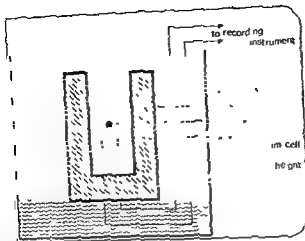

Fig 4 Arrangement for measuring the maximum temperature in polymerizing cements

succeeded in reducing the maximum temperature without affecting the manageability of the mixture.

To the Sulfix-6 powder and fluid in the ratio indicated by the manufacturer, an amount of high-viscosity CMC gel was added to make a mixture with 36 5 per cent (weight) gel The polymer powder : CMC gel , monomer fluid ratio was 5 4 2 Gel phase and resin phase in this mixture remained well distributed, which is to say that the gel formed a smooth outer layer on the surface.

In the centre of a test rod (fig 4) of 0.5 cu cm the maximum polymerization temperature of this cement remained between 50° and 60° C. In a similar test rod the commercial cement attained a temperature of 80-100° C (fig 5) In a globule of CMC cement kept in the hand, hardly any rise in temperature could be felt, and the temperature in vivo could be expected to be even lower because of the favourable heat release at the cement/bone interface (Debrunner 1975, Biehl et al. 1974). There were therefore sound reasons to presume that the temperature effect had been drastically reduced

It was likewise to be expected that the percentage of nonpolymerizing monomer would equal or slightly exceed (due to the low polymerization temperature) that in the conventional commercial bone cements.

The biphasic mixture of gel and cement will develop what may be described as a gel filled porosity, and this of course influences the mechanical properties also Since the aqueous gel phase is biodegradable (dissolves), it could be maintained that *a porous cement* had been ob-

Sulfix-6 is a new commercial product described by the manufacturer as different from products marketed earlier (Palacos, CMW and Simplex-P) in that it has a number of improved properties It is somewhat more finely granular and has a longer working time (Debrunner and Wettstein 1975a), because 15 per cent of the fluid consists of the co polymer n-butylmethacrylate, there is an indication of a (not significantly) lower maximum polymerization temperature at the cement surface (Debrunner 1974), and its lower porosity (Semlitsch 1975) is believed to give it slightly better mechanical properties than the other commercial acrylic cements There are no differences in monomer release (Debrunner and Wettstein 1975b), tissue toxicity of the cured product (Semlitsch 1973) and volumetric changes during polymerization (Debrunner 1975) As in Palacos, zirconium dioxide has been added to the polymer powder as radiopaque contrast medium The ratio polymer powder monomer fluid is 5 2 Conventional packings contain 40 g powder and 16 ml fluid

to J ■ de Wijn Chem E.)   ... ack ow edgement

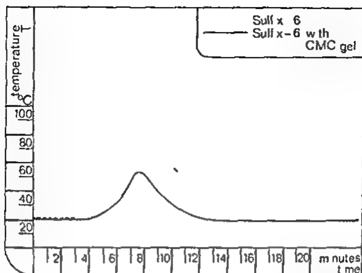

Fig 5 General shape of temperature time curve in laboratory tests The polymeriza tion time is the same for both types of cement

tained[1] The pores communicated and so formed a system with so called open porosity, in contrast with the closed porosity of commercial acrylic cements (fig 6) Porous implant materials, with all their advantages and disadvantages, are currently in the centre of interest For a brief discus sion we refer to chapter 5 For the design of this study it was of primary importance that a manageable cement was obtained in which the high maximum polymerization temperature was eliminated while the percent age of non polymerizing monomer remained about the same

The gel was a solution of 5 per cent sodium carboxymethylcellulose (CMC)* in water A 1 per cent aqueous solution of this CMC has a viscosity of 400 centipoise (CPs) The viscosity of the 5 per cent CMC gel used as measured with a Brookfield viscosimeter at 3 rpm was about 120 000 CPs

Carboxymethylcellulose is extensively used in the foods industry as wallpapering glue in rayon yarns and as constituent of synthetic detergents In pharmacology it is used as adjuvant in oral preparations and eye lotions and as catheter lubricant So far as could be established its toxicity to vascularized tissues is negligible

3 2 4 Sterilization

The polymer powder received from the manufacturer in the unster ilized form (Palacos and Sulfix) was divided into 10 g fractions which

were double-packed and gas-sterilized (ethylene oxide) In view of the toxicity of ethylene oxide (O'Leary and Guess 1968), the sterilized powder was not permitted to be used until 2 x 24 hours after sterilization (O'Leary et al 1968, Zagar 1972) No bacterial growth was ever found in samples which were bacteriologically examined The monomer fluid supplied by the manufacturer was sterile, and was divided into presterilized bottles under aseptic precautions The amounts for Palacos and Sulfix-6 were 5 ml and 4 ml, respectively

The CMC solution in water was sterilized in saturated water vapour at 100° C in a glass jar for 30 minutes and then, in a semi-liquid state, divided into sterilized eye-ointment tubes under aseptic precautions Because the viscosity diminished during sterilization due to thermic degradation of the CMC polymer (breakdown of chain length), we used a high-viscosity CMC sodium gel to start with This ensured that the product obtained after ultimate mixing with Sulfix-6 had the desired consistency

3 3 *Test animals*

The test animals used in the experiment were 166 young adult rabbits of the New-Zealand White strain They were selected because a large number of animals were needed and because adequate data are available on the vascularization of the rabbit femur The animals were about 4 months old, in good health, averaging 2465 g (range 1900-3400 g) body weight immediately before operation All were obtained from the same breeder and arrived at the animal laboratory at least 14 days before being used in the experiment They were accommodated in individual cages with grid floor, received water ad libitum and were fed a standard diet (standard mixture L K = 01 Hopefarms n v , Woerden, Netherlands)

The rabbits were randomly taken from the various litters and divided over the various groups (section 3 6) The sex distribution was likewise at random

In 4-month-old rabbits the growth plates have not yet closed The expected total longitudinal growth of the average rabbit femur is indicated in fig 7 The curve shown corresponds with the longitudinal growth pattern of the rabbit tibia indicated by Heikel (1960), in which the initially linear growth curve likewise declines after 100 days

3 4 *Operative technique*

The animals were fasted during 24 hours preceding the operation Anaesthesia was induced by intravenous injection of 0 5 mg atropine and 30 mg/kg pentobarbital sodium (Nembutal, S A Abbott n v , Amster-

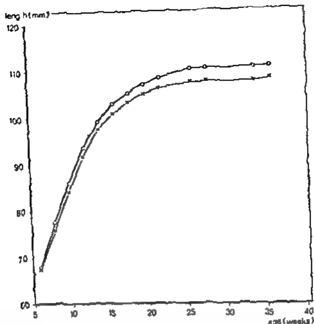

Fig 7 Longitudinal growth curves of the rabbit femur At age 6, 8, 10, 12, 14, 16, 18, 20, 22, 26, 28, 34 and 36 weeks, X rays were made of both femurs in a measuring-box especially designed for this purpose, under general anaesthesia. In this box the distances between focus and plate (66 5 cm) and between femur and plate (5 7 cm) remained constant On an OPTOCOM measuring table the coordinates (most distal end of lateral femur and most proximal end of greater trochanter) were established, whereupon the computer calculated the distances and plotted the mean curve for both femurs of 5 male (topcurve) and 5 female (bottomcurve) New Zealand White rabbits For calculation of the true femoral lengths, the values indicated in the two curves must be corrected by factor 0 914 (from a doctoral thesis by H. M van de Sandt Circumferential sectioning of the periosteum - in press)

dam) At the same time each animal received 50 mg/kg oxytetracycline (Terramycin, Pfizer Ltd, Sandwich, England) by intravenous injection as fluorochrome

After intubation the entire left hindleg was shaved and washed with Bethadine iodine soap and 70 per cent alcohol The animal was put on the table on its right side, lying on a water-heated mat and connected to a Keuskamp Amsterdam Infant Ventilator for ventilation with a mixture of oxygen and nitrous oxide (ratio 1 : 2) and 1 per cent halothane (Fluothane).

Sterility was ensured by observing precautions normally taken for any surgical intervention The left thigh was painted with iodine and, after sterile

were double-packed and gas sterilized (ethylene oxide) In view of the toxicity of ethylene oxide (O'Leary and Guess 1968), the sterilized powder was not permitted to be used until 2 x 24 hours after sterilization (O Leary et al 1968, Zagar 1972) No bacterial growth was ever found in samples which were bacteriologically examined The monomer fluid supplied by the manufacturer was sterile, and was divided into presterilized bottles under aseptic precautions The amounts for Palacos and Sulfix-6 were 5 ml and 4 ml, respectively

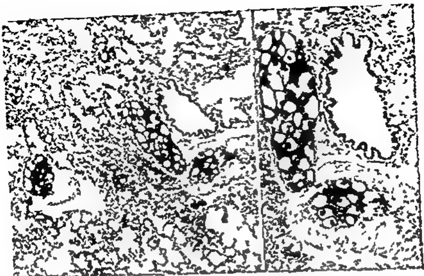
of monomer evaporating slowly in small amounts of set acrylic cement could thus be studied The operation was completed as indicated sub a)

c *Cementing* of the medullary cavity Bone cement (cf section 3 2) was prepared and, in a dough like state, pressed into a modified Impregum® syringe (ESPE GmbH, Seefeld, Austria) The syringe had been modified (fig 8) to correspond with the cement syringe designed for hip surgery by Slooff (1969, 1970) Syringe and Teflon tubing could be sterilized With the aid of a filler ring and plastic piston the cement was pressed into the cylinder until this was three-quarters full The syringe was then mounted and the screw spindle tightened until the acrylic cement emerged from the end of the tubing At that time the suction tube was replaced by the Teflon tubing of the cement syringe, which was inserted into the medullary cavity as far as the femoral condyles Slowly rotating the syringe, the entire medullary cavity was filled from the distal to the proximal end, while at the same time the syringe was slowly retracted This did not require much force because the tubing was pushed proximally by the cement filling the femur (fig 9) Usually, a thin trickle of cement escaped from the vent hole, and remnants of bone marrow (if any) escaped with it. The insertion and filling were done slowly, so that it took about 1 minute for the femur to be filled entirely Dependent on the size of the animal, the amount of cement introduced was 2 3 ml During this phase of the operation care was taken to ensure that the anaesthetic



draping, an incision of 1-2 cm was made over the greater trochanter This was stripped of its periosteum, and a manual drill with a diameter of 3 2 mm was then used for cautious reaming of the medullary cavity * The drill was introduced over a distance of 3 cm, whereupon the correct direction was determined with a guide-wire Drilling was then continued as far as the femoral condyles The medullary cavity was further widened with the aid of a second manual drill with a diameter of 4 0 mm Owing to the physiological antecurvature of the femur, reaming with this straight drill was possible only to about halfway the medullary cavity It was needed, however, because otherwise the Teflon tubing used for suction and cementing could not be readily inserted as far as the knee Via a second incision of 1 cm immediately proximal to the lateral femoral condyle, the periosteum was opened by means of a small longitudinal incision, the capsule was slightly pushed back and a burr hole was drilled in the cortex with a manual drill (burr diameter 1 6 mm)

A length of strong Teflon tubing (external diameter 4 mm, internal diameter 2 mm) was then inserted into the medullary cavity from the proximal end, connected with a suction tube, and slowly pushed down as far as the knee The diameter of this tubing was such that some pressure was required to insert it, and it was felt to scrape along the wall of the medullary cavity The tubing pushed most of the bone marrow away in front of it and this escaped through the vent near the lateral femoral condyle Bone marrow remnants were sucked away by moving the Teflon tubing up and down five times, until only clear blood was being sucked up After reaming and suction of the medullary cavity, the operation was continued in one of the following three ways

a *Closure* Fascia and skin of both incisions were closed with linen sutures while the animal was recovering from the anaesthesia After detubation the animal was placed on a blanket near a radiator in order to prevent heat loss

b *Insertion of a loose-fitting intramedullary rod* (Palacos®) A Palacos rod (diameter 3-4 mm, length 6-7 cm) was inserted from the proximal end and pushed in as far as the femoral condyles Any part still protruding was cut off with bone forceps The rods had been fashioned under sterile precautions a few hours earlier and had been kept sterile They could be expected to contain 2-5 per cent residual monomer (Smith and Baines 1956, Kutzner et al 1974a) The possible tissue-damaging effect

* The use of a powered drill was deliberately avoided because thermic damage cannot be excluded with any certainty (Danckwardt Lillieström 1969 Matthews and Hirsch 1972, Rhinelander 1974)

lung area

The wall of this branch is markedly thinned

which the medullary cavity was filled with Palacos after reaming and suction The operative technique initially used differed from that described in section 3.4 as used in the ultimate experiment no vent hole was drilled near the lateral femoral condyle, and the tubing of the syringe was not filled with cement to its very end.

In the first 7 animals operated on, peroperative and immediate postoperative mortality was high One animal had to be sacrificed because of a femoral shaft fracture which had occurred during reaming of the medullary cavity During or shortly after introduction of the cement, three animals showed pale sclerae and dilatation and downward displacement of the pupil, as well as an irregular heartbeat Ventilation with pure oxygen and external heart massage brought no improvement Spontaneous respiration was not resumed There appeared to be a respiratory standstill, the irregular heartbeat continuing for a few more minutes

During postmortem examination of the first animal to die in this manner, no macroscopical changes were seen However when the right ventricle was opened under water, there emerged air bubbles That air embolism had occurred was not surprising because an air column of about 7 cm length was introduced under pressure into the vascular bed, which had already been damaged as a result of the reaming This expe-

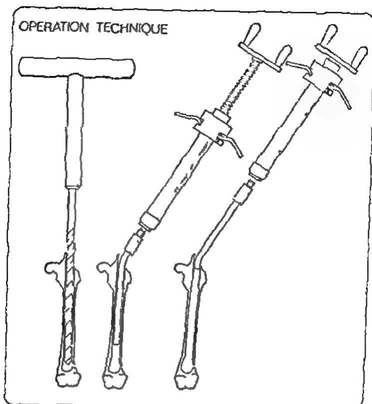


Fig 9 Operative technique Explanation in text pages 56, 57

was not allowed to become too deep The operation was completed as outlined sub a)

All operations were performed by the author, assisted by a biotechnician who gave the anaesthetic and an intern in orthopaedics The operation was simple and readily reproducible In all cases without exception the leg thus treated was capable of normal weight bearing after the operation, this could be checked because the animals had to stand erect on their hindlegs in order to reach their drinking-bottle There were no infections in the area of the operation, and no wound dehiscence occurred

3 5 *Preliminary experience and explanation of the operative technique used in the ultimate experiment*

3 5 1 Introduction

In order to gain an impression of the problems which might pose themselves during the experiment, a test group of 25 rabbits was used, in

by a few tenths of an atmosphere during insertion of the suction tube and during suction. A marked increase in intramedullary pressure occurred while the cement was being introduced. It was found that the pressure could be regulated by adjusting the rate of introduction of the cement. The mean rise in pressure in the 12 animals was up to 1.4 atmosphere. During rapid introduction of cement the pressure could rise to 2.5 atmospheres (end of the manometer scale). The increase in pressure sometimes persisted for some considerable time once the medullary cavity was completely filled (partly because the apertures in the screw were as a rule also filled with acrylic cement).

In each of the 12 animals the ECG showed accelerated sinus rhythm and lowering of the ST complex, indicative of coronary insufficiency. No straightforward correlation was established between the level of intramedullary pressure measured and the severity of the ECG changes. The 6 animals in which the system leaked, showed no ECG changes. Three animals in which the pressure rose to 1.8, 2.3 and 2.5 atmospheres, respectively, succumbed as a result of histologically verified pulmonary fat and bone marrow embolism. In these animals the ECG features were those of a changed electrical heart axis, increasing atrioventricular block with nodal extrasystoles, repolarization disorders and intraventricular conduction disorders (broadened QRS complex).

3.5.3 Discussion

The method used to measure intramedullary pressure had some unmistakable disadvantages: a manometer is not a precision instrument, registration is not possible, the occlusion ensured by the screw in the bone was often insufficient (with as a result a pressure measured too low), and the apertures in the screw filled with bone marrow remnants and sometimes with acrylic cement. These measurements were exclusively carried out to gain an impression of the rise in intramedullary pressure, and of the extent to which it could be „regulated" by quicker or slower tightening of the screw spindle of the cement syringe.

Even though these results, which closely resemble those reported by Marsman et al. (1975), warrant no absolute or generally valid conclusions, yet they helped in setting up the ultimate experiment. After reaming of the medullary cavity, a venthole was drilled immediately proximal to the lateral femoral condyle in all animals used in the ultimate experiment. This was done in order to

1. prevent an excessive rise in intramedullary pressure,
2. prevent massive pulmonary embolism,
3. ensure more complete removal of medullary contents,

rience taught us therefore to fill the entire length of Teflon tubing with cement before introducing the cement syringe

Of the other two animals, one developed irreversible shock shortly after insertion of the Teflon suction tube, and the other died shortly after introduction of the cement The deaths of these two animals (with macroscopically normal parenchymal organs at postmortem), however, could not be explained by an air embolism In these animals, massive fat and bone marrow embolisms were found in the lungs when frozen sections were stained with Sudan 4 (fig 10)

These complications did not occur when a lateral vent-hole was drilled in the distal segment of the femur, whereupon the cement was slowly introduced In view of studies by Danckwardt-Lillieström (1969) and Danckwardt-Lillieström et al (1970a, 1970b), it seems plausible that the cause of these fat embolisms had to be an increased intramedullary pressure during the operation In order to estimate the maximum possible increase in intramedullary pressure during the operation, this pressure was measured via a simple system in the next 18 animals It was also decided to monitor the ECG routinely

3 5 2 Determination of intramedullary pressure with simultaneous electrocardiographic registration

3 5 2 1 Method

A burr hole was drilled immediately proximal to the lateral femoral condyle, a screw thread was tapped and a modified hollow cortex screw (ASIF)* with a length of 20 mm was inserted and tightened as far as the opposite cortical layer Two apertures were made at the end of this screw Via a water-filled cannula, the screw was connected with a likewise water-filled standardized manometer The increase in intramedullary pressure was measured during insertion of the suction tube, suction of the medullary cavity, introduction of the cement, and setting of the cement

Throughout the operation, standard leads 1, 2 and 3 on 4 legs were used to register the heart action with the aid of a Mingograf 81 electrocardiograph (Elema-Schonander, Stockholm, Sweden) Arterial blood pressure, central venous pressure, cardiac output and blood gas values were not registered

3 5 2 2 *Results*

In 6 of the 18 animals the screw proved to occlude inadequately, and no pressure was measured In the remaining 12 rabbits the pressure rose

---

by a few tenths of an atmosphere during insertion of the suction tube and during suction A marked increase in intramedullary pressure occurred while the cement was being introduced It was found that the pressure could be regulated by adjusting the rate of introduction of the cement The mean rise in pressure in the 12 animals was up to 1 4 atmosphere During rapid introduction of cement the pressure could rise to 2 5 atmospheres (end of the manometer scale) The increase in pressure sometimes persisted for some considerable time once the medullary cavity was completely filled (partly because the apertures in the screw were as a rule also filled with acrylic cement)

In each of the 12 animals the ECG showed accelerated sinus rhythm and lowering of the ST complex, indicative of coronary insufficiency No straightforward correlation was established between the level of intramedullary pressure measured and the severity of the ECG changes The 6 animals in which the system leaked, showed no ECG changes Three animals in which the pressure rose to 1 8, 2 3 and 2 5 atmospheres, respectively, succumbed as a result of histologically verified pulmonary fat and bone marrow embolism In these animals the ECG features were those of a changed electrical heart axis, increasing atrioventricular block with nodal extrasystoles, repolarization disorders and intraventricular conduction disorders (broadened QRS complex)

3 5 3 Discussion

The method used to measure intramedullary pressure had some unmistakable disadvantages a manometer is not a precision instrument, registration is not possible, the occlusion ensured by the screw in the bone was often insufficient (with as a result a pressure measured too low), and the apertures in the screw filled with bone marrow remnants and sometimes with acrylic cement These measurements were exclusively carried out to gain an impression of the rise in intramedullary pressure, and of the extent to which it could be „regulated' by quicker or slower tightening of the screw spindle of the cement syringe

Even though these results, which closely resemble those reported by Marsman et al (1975), warrant no absolute or generally valid conclusions, yet they helped in setting up the ultimate experiment After reaming of the medullary cavity, a venthole was drilled immediately proximal to the lateral femoral condyle in all animals used in the ultimate *experiment* This was done in order to

1 prevent an excessive rise in intramedullary pressure,
2 prevent massive pulmonary embolism,
3 ensure more complete removal of medullary contents,

4 minimize the risk of intracortical bone marrow embolism which, through obliteration of vascular canals, can greatly contribute to cortical necrosis (Danckwardt-Lillieström et al 1970b)

In the elegant experiment which Kallos et al (1974) published after completion of this study, the direct correlation between high intramedullary pressure and pulmonary fat embolism was incontrovertably demonstrated

During digital introduction of acrylic cement and a stainless steel rod in the cement mass into dog femurs they measured intramedullary pressures of 290 900 mm Hg with the aid of a tracer (^{99m}Tc macroaggregated albumin) injected into the medullary cavity they established that medullary contents appeared in the lungs within 10 120 seconds When a vent hole was made in the femur, the intramedullary pressure did not rise beyond 1 93 mm Hg and no increase in radioactivity was observed in the lungs Histological examination revealed fairly large fat globules in the lungs of dogs with non vented femurs, whereas only a few small globules were observed in the lungs of dogs whose femurs had been vented previously

3 5 4 Conclusion

In view of preliminary experience gained with 25 rabbits used as a test group, we opted for drilling a vent-hole in the lateral distal femur in all animals used in the ultimate experiment

3 6 *Division into groups*

The animals were classified according to type of operation and type of acrylic cement used (table 1) The seven groups included 18 animals each (table 2) Intercurrently deceased or disqualified animals (section 3 13) were replaced As described in section 3 4, the operation was always performed on the left femur, the right femur serving as control An exception was made for groups 1 and 3a, which represent bilateral

Table 1 Grouping according to type of operation

Group	Type of operation
1	Reaming and suction of medullary cavity (RS)
2	RS + Palacos rod
3a	RS + commercial acrylic cement (Palacos)
3b	RS + commercial acrylic cement (Sulfix 6)
4a	RS + acrylic cement (Palacos) without catalyst
4b	RS + acrylic cement (Sulfix 6) without catalyst
5	RS + modified acrylic cement Sulfix-6 with CMC gel

4 minimize the risk of intracortical bone marrow embolism which, through obliteration of vascular canals, can greatly contribute to cortical necrosis (Danckwardt-Lillieström et al 1970b)

In the elegant experiment which Kallos et al (1974) published after completion of this study, the direct correlation between high intramedullary pressure and pulmonary fat embolism was incontrovertably demonstrated

During digital introduction of acrylic cement and a stainless steel rod in the cement mass into dog femurs they measured intramedullary pressures of 290 900 mm Hg *with the aid of a tracer* (^{99m}Tc macroaggregated albumin) injected into the medullary cavity they established that medullary contents appeared in the lungs within 10 120 seconds When a vent hole was made in the femur, the intramedullary pressure did not rise beyond 1 93 mm Hg and no increase in radioactivity was observed in the lungs Histological examination revealed fairly large fat globules in the lungs of dogs with non vented femurs, whereas only a few small globules were observed in the lungs of dogs whose femurs had been vented previously

3 5 4 Conclusion

In view of preliminary experience gained with 25 rabbits used as a test group, we opted for drilling a vent-hole in the lateral distal femur in all animals used in the ultimate experiment

3 6 *Division into groups*

The animals were classified according to type of operation and type of acrylic cement used (table 1) The seven groups included 18 animals each (table 2) Intercurrently deceased or disqualified animals (section 3 13) were replaced As described in section 3 4, the operation was always performed on the left femur, the right femur serving as control An exception was made for groups 1 and 3a, which represent bilateral

Table 1 Grouping according to type of operation

Group	Type of operation
1	Reaming and suction of medullary cavity (RS)
2	RS + Palacos rod
3a	RS + commercial acrylic cement (Palacos)
3b	RS + commercial acrylic cement (Sulfix-6)
4a	RS + acrylic cement (Palacos) without catalyst
4b	RS + acrylic cement (Sulfix-6) without catalyst
5	RS + modified acrylic cement Sulfix-6 with CMC gel

after operation and once a week thereafter The purpose was to evaluate whether the method of cementing was sufficient (i e whether the entire femur was filled with cement) and to establish whether fractures had occurred during the operation or became manifest after the operation In addition, it was expected that the femurs treated by operation would increase in circumference, as has been the case in the studies of Slooff (1970, 1971), who introduced acrylic cement into the medullary cavity in dogs The radiological follow up was made to establish whether the same could be observed in rabbit femurs

3 8 1 1 *Method*

[illegible] intramuscular injection of 0.5 ml/kg *Hypnorm (Philips* [illegible]

3 8 1 2 *Results*

The medullary cavities of all femurs except two were entirely filled with acrylic cement. In one animal an avulsion fracture of the femoral diaphysis was observed which had been overlooked at operation The mean increase in femoral circumference was small A thin low-contrast layer of periosteal bone apposition was usually visible along the entire cortex from the second postoperative week on The layer attained its maximum thickness after 3 weeks and in the 14 animals with completely cement filled medullary cavities, caused a mean increase in circumference of 9 per cent, as measured on a fixed point at the centre of the diaphysis. Subsequently the density of this new bone increased, and no further radiological changes occurred after 7 weeks.

3 8 1 3 Discussion

The enormous bone apposition which Slooff (1970, 1971) observed in cemented dog femurs, was not found in rabbit femurs Since the above described radiographic method was rather cumbersome, since the animals' biorhythm was being disturbed every week, and since the information obtained was of little value, these radiographs were not included in the ultimate experiment

3 8 1 4 Conclusion

As weekly radiographic follow up failed to yield anything of value, it was abandoned for the animals in the ultimate experiment Immediately after operation a radiograph was always obtained to make sure that the entire medullary cavity was filled with cement and to ascertain that no fracture had occurred

operations operations on the left femur formed group 3a, and operations on the right femur formed group 1 The animals were paired off for sacrifice 1, 2, 3, 4, 5, 6, 7 weeks and 3 and 6 months after operation This means that for every survival period 2 animals per group were available for examination Finally, 6 animals were kept alive until 9, 12 and 24 months after the operation (table 2) They were the 6 animals of the test group in which determination of intramedullary pressure had shown no rise due to leakage along the screw It could therefore be assumed that no significant rise in intramedullary pressure had occurred The acrylic cement used in these cases was Palacos (section 3 5 2)

3 7 *Sacrificing technique*

After intravenous injection of 50 mg (5000 IU) heparin, the animals were sacrificed by intravenous injection of an overdose of pentobarbital sodium (Nembutal) Immediately after cardiac arrest the abdominal cavity was opened and the aorta was cannulated at the level of the renal arteries with a plastic cannula inserted almost as far as the bifurcation The aorta was ligated proximal to the site of cannulation The inferior vena cava was opened From a constant height of 100 cm (the most common physiological perfusion pressure) irrigation was effected with 1 litre physiological saline The cannula was then connected with an infusion flask filled with a Micropaque® suspension * This was a 6 per cent barium sulphate solution made from Micropaque 70 per cent W/W fine-granular barium sulphate and 35 g sodium citrate in 1 litre physiological saline The first 300 ml of this solution could be run in quickly, the rest followed at a steady drip As a rule, the suspension freely escaped from the inferior vena cava after about 1 minute It took about 90 minutes for perfusion of the total amount of 1000 ml Micropaque suspension to be completed The perfusion pressure was not measured Next, both femurs were exarticulated in hip-joint and knee-joint, leaving an ample muscular cover in order to leave the periosteum intact The bones were immediately numbered, packed in plastic bags and deep-frozen to –18° C

3 8 *Radiological technique*

3 8 1 Radiographs during the period of observation

In the animals of the test group, radiographs of the pelvis and both femurs were made by a standard method before operation, immediately

* Micropaque® (Microtrast) Oesophageal Cream is supplied by Damancie & Cy Ltd Slough (Bucks), Great Britain

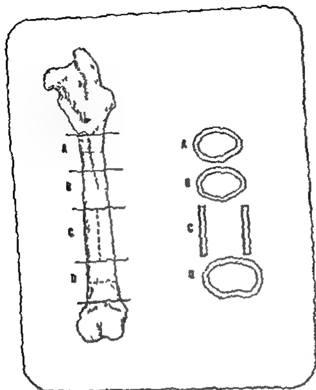

Fig 11 Schematic representation of segments used for decalcified and non decalcified sections

decalcified sections thus obtained were embedded as a histological section with a non fluorescent adhesive (DPX) and studied with the fluorescence microscope (section 3 11) The procedure described caused disappearance of acrylic cement from the bone by *dissolution in trichloracetic acid*, toluene, *chloroform*, xylol and acetone

3 10 *Microangiography*

To obtain microangiograms of the non-decalcified sections from segments A, B, C and D of left and right femur, use was made of a microradiogram arrangement with a Philips self rectifying X-ray generator type PW 1008 and Kodak spectroscopic safety film type 649-0 (20 min, 20 kV, 30 mA) The sections were placed directly on the film, the distance from the tube being 20 cm The microradiograms obtained were placed on a slide and examined with the light microscope

3 8 2 Postmortem radiographs

To assess the degree of filling of vessels with Micropaque, radiographs were made in two directions of all deep-frozen femurs, using mammography equipment with a molybdenum anode Very fine-grained industrial roentgen film was used so that enlargements were possible if required This technique has been found very suitable for evaluation of bone structure (Meema et al 1972, Hendriks 1975)

3 9 *Histological technique*

Of the deep-frozen femurs with soft-tissue lining, only the diaphysis and a small part of the lower methaphysis were used This was manually cut into 7 transverse segments of about 0 75 cm thickness, which were numbered A, B, C and D from proximal to distal end Segment C was bisected longitudinally, thus giving a total of 8 bone fragments Of each segment A, B, C and D, one half was decalcified for paraffin processing and the other half was not decalcified but destined for embedding in plastic The segments A, B and D were cut into transverse, and segment C into longitudinal sections (fig 11) The procedure to obtain paraffin sections was decalcification during 2 days in 5 per cent trichloracetic acid (which is also a fixative fluid which ensures persistent stainability), followed by washing with 90 per cent alcohol for 1 hour and then dehydration with 70 per cent alcohol, 80 per cent alcohol and 90 per cent alcohol and toluene (each during 24 hours), finally followed by degreasing with chloroform during 12 hours Next, the tissue fragments were soaked in paraffin during 12 hours in an incubator at 60° C to ensure evaporation of the chloroform The fragments were then embedded in paraffin and a Leitz microtome was used to cut 5 micra sections These sections were stained with haematoxylin eosin and according to Goldner (Romeis 1968, Schenk et al 1969) The Goldner stain gives non-mineralized connective tissue (e g osteoid) an orange red colour, bone stains green, cells black, cytoplasm orange and muscular tissue reddish-violet

The procedure to obtain the non decalcified sections was fixation in 70 per cent alcohol during about 16 hours, followed by dehydration with 80 per cent alcohol, 96 per cent alcohol, 100 per cent alcohol, acetone and toluene (each during 24 hours) The slices were then embedded in methylmethacrylate and, after curing, cut into 110 micra sections with a diamond section-cutting machine (instrument workshop, Department of Dentistry, University of Groningen) These sections were polished on both sides (Kent MK_2 polishing machine, Engis, Alphen a/d Rijn, Netherlands) until a thickness of 100 micra was attained They were not stained The non-

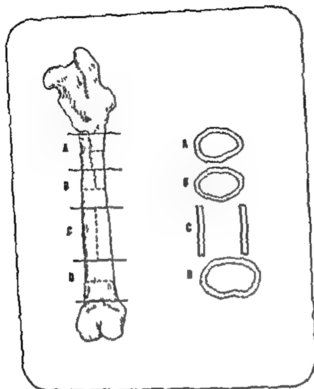

Fig 11 Schematic representation of segments used for decalcified and non decalcified sections

decalcified sections thus obtained were embedded as a histological section with a non-fluorescent adhesive (DPX) and studied with the fluorescence *microscope (section 3 11)* The procedure described caused disappearance of acrylic cement from the bone by dissolution in trichloracetic acid, toluene, chloroform, xylol and acetone.

3 10 *Microangiography*

To obtain microangiograms of the non-decalcified sections from segments A, B, C and D of left and right femur, use was made of a microradiogram arrangement with a Philips self-rectifying X-ray generator type PW 1008 and Kodak spectroscopic safety film type 649-0 (20 min; 20 kV, 30 mA) The sections were placed directly on the film, the distance from the tube being 20 cm The microradiograms obtained were placed on a slide and examined with the light microscope.

3.8.2 Postmortem radiographs

To assess the degree of filling of vessels with Micropaque, radiographs were made in two directions of all deep-frozen femurs, using mammography equipment with a molybdenum anode. Very fine-grained industrial roentgen film was used so that enlargements were possible if required. This technique has been found very suitable for evaluation of bone structure (Meema et al. 1972, Hendriks 1975).

3.9 *Histological technique*

Of the deep-frozen femurs with soft-tissue lining, only the diaphysis and a small part of the lower methaphysis were used. This was manually cut into 7 transverse segments of about 0.75 cm thickness, which were numbered A, B, C and D from proximal to distal end. Segment C was bisected longitudinally, thus giving a total of 8 bone fragments. Of each segment A, B, C and D, one half was decalcified for paraffin processing and the other half was not decalcified but destined for embedding in plastic. The segments A, B and D were cut into transverse, and segment C into longitudinal sections (fig. 11). The procedure to obtain paraffin sections was: decalcification during 2 days in 5 per cent trichloracetic acid (which is also a fixative fluid which ensures persistent stainability), followed by washing with 90 per cent alcohol for 1 hour and then dehydration with 70 per cent alcohol, 80 per cent alcohol and 90 per cent alcohol and toluene (each during 24 hours), finally followed by degreasing with chloroform during 12 hours. Next, the tissue fragments were soaked in paraffin during 12 hours in an incubator at 60° C to ensure evaporation of the chloroform. The fragments were then embedded in paraffin and a Leitz microtome was used to cut 5 micra sections. These sections were stained with haematoxylin-eosin and according to Goldner (Romeis 1968, Schenk et al. 1969). The Goldner stain gives non-mineralized connective tissue (e.g. osteoid) an orange red colour, bone stains green, cells black, cytoplasm orange and muscular tissue reddish-violet.

The procedure to obtain the non-decalcified sections was: fixation in 70 per cent alcohol during about 16 hours, followed by dehydration with 80 per cent alcohol, 96 per cent alcohol, 100 per cent alcohol, acetone and toluene (each during 24 hours). The slices were then embedded in methylmethacrylate and, after curing, cut into 110 micra sections with a diamond section-cutting machine (instrument workshop, Department of Dentistry, University of Groningen). These sections were polished on both sides (Kent MK_2 polishing machine, Engis, Alphen a/d Rijn, Netherlands) until a thickness of 100 micra was attained. They were not stained. The non-

mycin® Pfizer),
Red 8 as 1 per c.

For the animals used for macro-autoradiography, no exception was made to this rule, in view of the possibility that Terramycin in the dose given could have a slight inhibitory effect of bone formation (Danckwardt Lilliestrom 1969, Rahn 1973) The two animals which survived 7 weeks after operation in each of the groups 1 through 5, were in addition given weekly one of the above-mentioned newer fluorochromes as 3 per cent sterile solution (Rahn and Perren 1970, 1971, 1972) according to the plan shown in table 3

To study and photograph the sections we used a modified Zeiss Universal microscope with fluorescence equipment, the vertical illuminator III RS and the attached camera LS Matic (Verhofstad and Schrijer, 1975) Incident light excitation was used In relation to the light direction, the sequence of the optical system used was as follows

Light source	high pressure mercury vapour lamp OSRAM HBO 200 W/4 heat absorption filter KG 1 red absorption filter BG 38
III RS (position 3) with (blue light excitation)	excitation interference blue filter KP 500 excitation interference blue filter KP 490 dichroitic interference mirror FT 510 barrier filter LP 520
or III RS (position 1) with (UV excitation)	UV permeable black glass UG 1 dichroitic interference mirror FT 420 UV barrier filter LP 418
Objective	Neofluar 63 0 2

For the colour reproductions presented in chapter 4 only position 3 of the vertical illuminator III RS was used the calcein blue which fluoresced only in position 1, is therefore not visible in these reproductions (table 3) The colour as reproduced on the film used (daylight film Kodak HS 23° DIN Ektachrom EH 135) visually corresponded with the colour of the microscope image Exposure times were 2 20 seconds.

3 12 *Macro-autoradiography*

Autoradiography shows the distribution of radioisotope labelled compounds over the various tissues Bone seeking radioisotopes are deposited in new and incompletely mineralized osteons and make it possible qualitatively to demonstrate distribution patterns in bone and such processes as growth and repair In combination with histological and fluorescence techniques it can be used to differentiate between processes of bone *degeneration and bone regeneration*

To put it simply, the image produced by the radioactivity from a sample on a photographic emulsion is an autoradiogram On the developed film, the sites where the radioactive element is localized appear as dark areas The Strontium ion used in this study so closely resembles

3.11 *Fluorochrome labelling*

Ordinary histological sections do no justice to the dynamics of such processes as growth, remodelling and regeneration of bone. The use of vital staining agents which are bound to newly formed bone of any origin (Harris 1960, Harris et al. 1964, Frost 1969) has added a new dimension to the study of these dynamic processes.

In addition to the best-known fluorochromes, the tetracyclines (Milch et al. 1958, Harris 1960, Harris et al. 1962), a need has arisen for other vital staining agents to be used in sequential labelling (Olerud and Lorenzi 1970, Rahn 1973). Alizarin Red S is perhaps too toxic (Harris 1960, Adkins 1965). Moreover, it has been reported to inhibit bone formation (Harris et al. 1964), although others have refuted this (Vilmann 1969). Olerud and Lorenzi (1970) used it only immediately before sacrificing the test animal.

Fluorochromes for experimental use which have a low systemic toxicity and no local effect on calcification, and at the same time give clearly defined colour differences, are calcein (Suzuki and Mathews 1966), calcein blue (Rahn and Perren 1970), xylenol orange (Rahn and Perren 1971) and Alizarin-complexon (Rahn and Perren 1972).

During induction of anaesthesia, all the animals used in the experiment received an intravenous injection of 50 mg/kg oxytetracycline (Terra-

Table 3 Fluorochromes given for sequential labelling to the animals observed over a period of 7 weeks

3.14 *Summary*

In 7 x 18 rabbits femurs the medullary cavity was reamed, a vent hole was drilled and the medullary contents were removed by suction. In view of preliminary experience with a test group of 25 animals, the vent hole was drilled as routine procedure.

The procedure was continued by filling the medullary cavity with acrylic cement. Dependent on the type of acrylic cement used, the animals were divided into 7 groups:

- — only reaming and suction (group 1),
- — insertion of a loose fitting intramedullary Palacos rod (group 2),
- — filling of the medullary cavity with commercial acrylic cement (groups 3a and 3b),
- — filling with acrylic „cement" without catalyst (groups 4a and 4b)
- — filling with a modified acrylic cement Sulfix-6 with CMC gel (group 5)

The animals were sacrificed in pairs 1, 2, 3, 4, 5, 6 and 7 weeks and 3 and 6 months after operation, and the lower limbs were perfused with a Micropaque suspension. The femurs were processed for radiological, histological, microangiographic and fluorescence microscopic examination. The acrylic cement dissolved during processing of microscopic sections. Six animals in which commercial acrylic cement had been implanted were followed up over periods of 9, 12 and 24 months. Of 10 animals from each group (1, 2, 3a, 4a and 5), the femurs were used for macro-autoradiography after 1 or 4 weeks. In 2 animals from each of the two groups 4a and 5, an autoradiogram was made after 4 months

the calcium ion that it is incorporated in bone crystals in an identical way. Sr^{89} is a beta-emitter with a half-life of 51 days (McLean and Budy 1964).

The femurs of 10 rabbits (2 from each of the 5 principal groups) were macro-autoradiographically studied 1 and 4 weeks after operation. In 2 rabbits from groups 4a and 5, an autoradiogram was made after 4 *months (table* 4).

The survival of rabbits after injection of 80 μCi ^{89}Sr - $SrCl_2$ in aqueous solution (Amersham) was always 24 hours. Immediately after sacrificing the animals, both femurs were removed and immersed for 10 minutes in a chilling mixture of dry ice and isopentane (–65° C to –75° C). Until further processing the bones were stored in a freezer at –18° C. The bones were fixed by embedding them in a suspension of carboxymethylcellulose in water (5 per cent, medium viscosity, temperature 0° C). After embedding the bones the CMC suspension was frozen by chilling it to –15° C. The CMC bloc was mounted on the movable stage of a microtome (Jung K) placed in a freezer (–15° C). Sections of 30 micra thickness were fixed on tape (Scotch 810 3AW) during cutting. The strips of tape were then stretched on cardboard sheets. Before a film (Agfa-Gevaert Structurix D7) was placed on the fixed sections, it was dried in a freezer (–18° C) during 48 hours. The exposure time of the film was about 5 days.

Table 4. The animals used for Sr^{89} macro-autoradiography, classified according to type of operation and period of observation.

Rabbit no.	Group	Type of operation	*Survival in weeks*
6463	1	RS*	1
6464	1	RS	4
6559	2	RS + Palacos rod	1
6481	2	RS + Palacos rod	4
6456	3a	RS + Palacos	1
6457	3a	RS + Palacos	4
6458	4a	RS + Palacos without catalyst	1

will be discussed under the joint heading group 4 RS + PMMA without catalyst

The photomicrographs shown are representative of the group and observation period concerned

The photomicrographs of histological sections shown in this section depict haematoxylin-eosin (HE) stains. The photomicrographs were made with the Leitz Orthomat on Scientia film 50-B-65 A green filter 546 nm was used in the exposures. The periosteum is always shown at the top of the photograph and details are viewed from the endosteal cortex side The legends to the figures mention in succession observation period, group, femur involved rabbit number, segment number (A, B, C or D) and if necessary type of cement
Pa (= group 3A commercial Palacos)
Su (= group 3B commercial Sulfix-6)
Pa–C (= group 4A Palacos without catalyst)
Su–C (= group 4B Sulfix-6 without catalyst)

To summarize the groups to be discussed in the following sections will be referred to as

- group 1 reaming (R) and suction (S)
- group 2 RS + Palacos Rod
- group 3 RS + PMMA
- group 4 RS + PMMA without catalyst
- group 5 RS + modified Sulfix-6 with CMC gel

4 2 *Macroscopic findings*

Apart from a sligthly larger diameter as compared with the control bone, the deep-frozen femurs showed no relevant changes Near the lateral femoral condyle at the site of the vent hole, some callus tissue was usually found The distal cut surface was chosen in such a way that this callus tissue did not fall in the most distal sector (D) Once the femurs were cut into sections it was invariably found that the acrylic cement always filled the entire medullary cavity and was always fixed firmly to the bone, regardless of the type of cement used This did not apply to the loose fitting rods in group 2, these, however, were encapsulated by regenerated bone marrow

4 3 *The normal histological features of the other femur used as control*

The normal histological features of the transverse section of the control femur show, throughout the specimen, osteons with vital osteocytes

CHAPTER 4

RESULTS

4 1 *Premises*

The typical reactions which occur in medullary cavity, cortex and periosteum following an intramedullary intervention have been described in detail in chapter 2 The same reproducible histological changes were observed also in our material, and need not be discussed in detail again in this chapter

In this discussion of results, emphasis will be placed on a *comparison* of the changes observed in the various groups In all cases sections of the treated femur were also compared with those of the control femur Since no measurements were made, the observations are only graphic and descriptive, and not suitable for statistical analysis

The histological sections provided the basis for the material studied All other investigations were complementary and helped to confirm the observations made on the histological material To avoid repetition, the entire histological material, including the fluorescence-microscopic findings, will be collectively discussed in sections 4 3 and 4 4 An exception will be made for the animals studied by sequential fluorochrome labelling during 7 weeks (sections 4 6 and 4 7)

In the Goldner-stained sections the distribution and intensity of stained osteoid varied from section to section Sometimes the osteoid was stained in one animal but not in the other On the whole, the data obtained provided too little constant information to warrant definite conclusions A detailed discussion would be detrimental to the surveyability of this documentation

It was also found that longitudinal sections C (fig 11) supplied no new information, shortly after the start of the ultimate experiment, therefore section C was used for making transverse sections

Since no essential differences in the reaction pattern of cortex, medullary cavity and periosteum were observed in the material from groups 3A (commercial acrylic cement Palacos) and 3B (commercial acrylic cement Sulfix-6), the two groups will be discussed under the joint heading group 3 RS + PMMA The same applies to groups 4A and 4B, which

The normal histological features of the transverse section of the control femur show, throughout the specimen, osteons with vital osteocytes

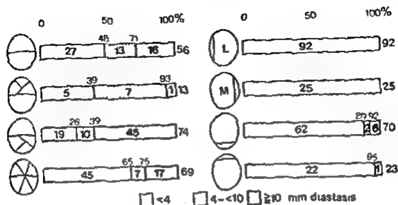

Fig 6 Separation of the fragments in various types of patellar fracture

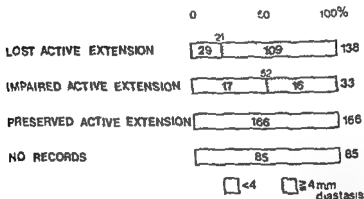

Fig 7 Function of the quadriceps apparatus with respect to separation of the fragments in 416 patients with 422 patellar fractures

Of the patients who were considered to suffer from loss of active function of the quadriceps apparatus 109 (79%) had a separation between the fracture parts of at least 4 mm (Fig 7) The diastasis did not exceed 5 mm in any of the 16 patients who had impaired active extension of the knee

A step in the articular surface of the patella of 3 mm or more, in concomitant diastasis less than 4 mm was found in six patients (Fig 8) Five of these had preserved active extension of the knee while one had loss of active extension

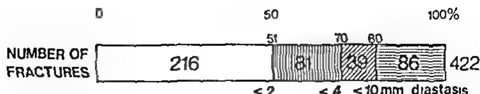

Fig 4 Distribution of 422 patellar fractures with respect to separation of the fragments

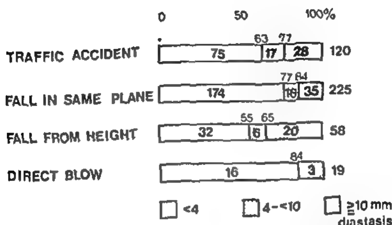

Fig 5 Distribution of 422 patellar fractures with regard to various modes of injury and resulting separation of the fragments

than 10 mm, and as considerable, if the separation between the fragments was at least 10 mm There was no dislocation in 216 fractures (51%), Fig 4 In a further 19 per cent the diastasis was less than 4 mm In 125 fractures (30%) the diastasis was 4 mm or more Of these, 86 fractures (20%) had a diastasis of at least 10 mm

Considerable diastasis was observed in 35 per cent of the fractures caused by fall from height (Fig 5) The diastasis was often slight in falling in the same plane

Transverse fractures with a split lower pole were often dislocated In 61 per cent there was a separation between the fragments of at least 10 mm (Fig 6) Considerable diastasis was established also in transverse fractures with two large fragments (29%) and in comminuted fractures (25%) Only in exceptional cases was there a considerable diastasis in transverse fractures with a split upper pole as well as in apical and basal fractures In longitudinal fractures the diastasis did not in any case exceed 4 mm

(68%) and operative treatment on 135 fractures in 134 patients (32%) The distribution of non surgical and surgical treatment with regard to various age groups among males and females is tabulated in Fig 9

The methods used in non surgical treatment are mentioned in Table 11

Non surgical treatment, as a rule, included immobilization in plaster reaching from the malleoli to the inguen In some cases the haematoma in the knee was first punctured An elastic adhesive bandage was regarded as adequate in some cases, whilst in others no treatment was considered necessary

Of the 282 non surgically treated patients, 214 were ambulant and 68 were treated as in patients The median period of hospitalization was six days

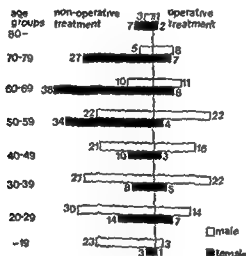

Fig 9 Non operative and operative treatment of 416 males and females of different ages with patellar fracture

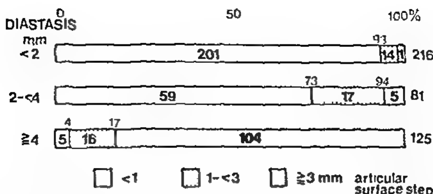

Fig 1 Relation between diastasis and articular surface step in 422 patellar fractures

Treatment

On the same day of the trauma 306 patients (74%) came for treatment to the hospital and 83 (20%) within a week The remaining 27 (6%) did not come to the hospital until one week or more had elapsed 202 (48%) were treated as in patients

The treatment was given at Ekmanska sjukhuset (1/1–15/10 1959) at the two Clinics of Orthopaedic Surgery and at the Surgical Clinics

The treatment was selected according to the following principles Non operative methods were considered applicable if the difference in level between the fragments was less than 3 mm if the patient could lift his leg with his knee extended and/or if the diastasis between the fracture parts was less than 4 mm If there was loss of active extension despite the diastasis being less than 4 mm the patients were hospitalized If the extension capability was restored—possibly after puncture of the joint—the patients were not subjected to surgery In all the other cases surgery was indicated

Owing to loss of active extension eleven patients were surgically treated despite the diastasis between the fragments being less than 4 mm In four cases it was stated that the lateral expansions were uninjured and in two that they were torn In five cases the statements were unreliable

Five patients were surgically treated despite there not being any loss of active extension and despite the diastasis between the fragments being less than 4 mm In these cases the lateral expansions were uninjured

Six patients were not operated on despite the diastasis between the fracture parts being 4 mm or more Of these five had impaired active function of extension and one patient had sustained polio and wore a lower extremity support

Non operative treatment was performed on 287 fractures in 282 patients

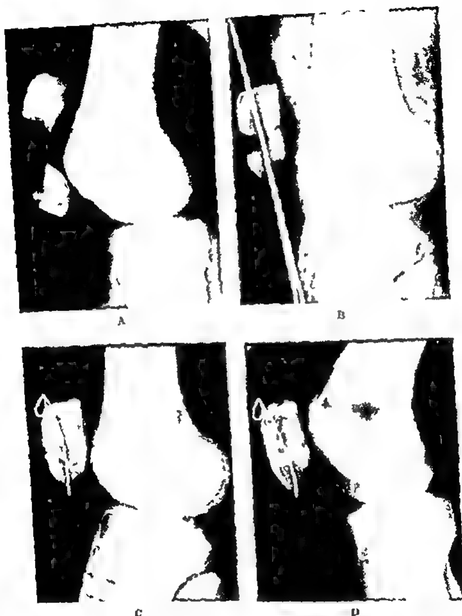

Fig. 11. See text on page 36

The main principle was to restore the normal anatomy of the patella. The most common method of operation was osteosynthesis with a stainless steel wire inserted through two longitudinally drilled holes. In principle the operation was performed as follows. The operation was made in a bloodless field

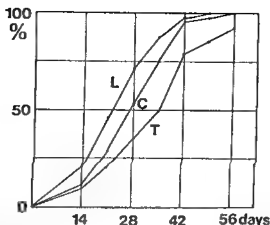

Fig 10 Cumulative distribution graphs showing period of immobilization in plaster cast in various non operatively treated types of patellar fracture (L=longitudinal fractures C=comminuted fractures, T=all types of transverse fractures)

Table 12 Surgical methods of treatment for various types of patellar fracture 'Other methods for osteosynthesis were metal pin (one case) metal wire through cross drilled holes (two cases), suture with silk linen or catgut (five cases)

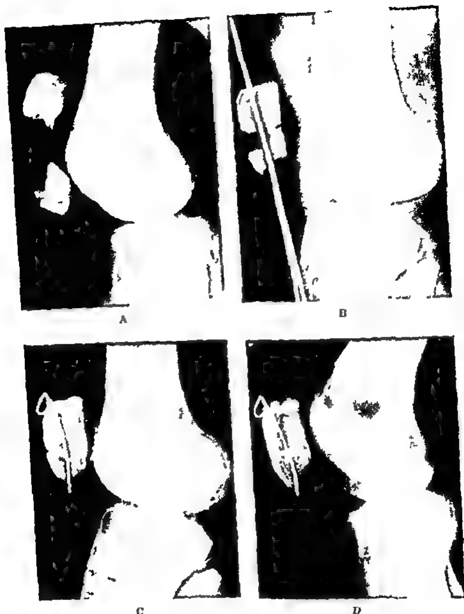
The approximate median period of immobilization in plaster after non surgical treatment was four weeks and shorter for longitudinal fractures than for transverse and comminuted (Fig 10)

When there was an indication for surgery the operation was performed on the same day or on that following The methods of operation employed are given in Table 12



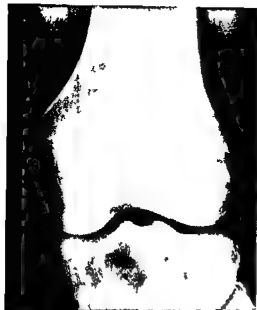


Fig 11 See text on page 36

The main principle was to restore the normal anatomy of the patella The most common method of operation was osteosynthesis with a stainless steel wire inserted through two longitudinally drilled holes In principle the operation was performed as follows The operation was made in a bloodless field

E

F

Fig 11 Transverse fracture of the patella with two large fragments (A) treated by osteosynthesis with metal wire through longitudinally drilled holes (B–C) B shows two Kirschner wires piercing the fragments (The result eight years later (D F) was excellent)

After making a medial parapatellar incision the prepatellar bursa was extirpated The joint cavity was syringed carefully with physiological saline solution The tear of the lateral expansions was identified After removing any small fragments the fracture parts were fastened together by means of bone clamps Two Kirschner wires with a needle's eye were drilled parallelly into the proximal fragment starting at the basis (Fig 11) As it was often impossible to drill through both fragments at the same time the wires were drilled across the line of the fracture far enough to allow distinct impressions to be made in the distal fragment This indicated where another pair of Kirschner wires could be inserted A 0 9 mm stainless steel wire was attached to the Kirschner wires and drawn back to the basis where it was tightened with a wire twister Then the wire ends were recessed into a channel made with an awl in the basis of the patella Restoration of the articular surface was very much facilitated by inserting a finger into the joint and at the same time hyperextending the knee thus permitting the articular surface to be palpated (Moberg 1944) *After completing the osteosynthesis the tear of the lateral* expansions was repaired with catgut or silk

Partial patellectomy retaining one large fragment was the most important alternative to osteosynthesis and was mainly used in transverse fracture with a split lower pole (Fig 12)

later (C) was excellent)

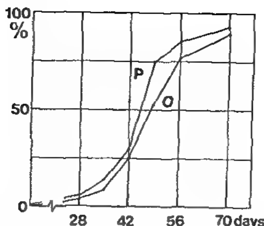

Fig 13 Cumulative distribution graphs showing duration of immobilization in plaster cast in patellar fractures treated by osteosynthesis and partial patellectomy (P=partial patellectomy, O=osteosynthesis)

Only in exceptional cases—in open fractures—was the patella completely excised

In open injuries the fracture was surgically treated in 19 out of 23 cases The operation was performed at the acute stage with one exception In nine cases osteosynthesis was carried out in five the patella was partly excised and in another five total patellectomy was performed

After the operation the leg was immobilized in a plaster cast reaching from the malleoli to the inguen and the knee was fixed in a flexed position of 5–10 degrees As a rule there was no drainage Generally the patient remained in bed for 3–4 days after the operation with the leg elevated Isometric exercise of the quadriceps muscle was begun on the day after the operation After a few days leg raising exercises were instituted Crutches were used after the mobilization as protecting support but weight bearing was allowed

The median period of hospitalization in operative treatment was twelve days

The median period of immobilization in plaster cast was 6 5 weeks (Fig 13) This period did not vary with the methods of operation

When the plaster cast had been removed the patient was given verbal instructions about extension and flexion exercises A physiotherapist super vised when necessary

Complications

No patient died owing to fracture of the patella There were complications in 19 patients (5%) Table 13

Four patients sustained refracture after osteosynthesis In three of these cases the operation had been performed with a stainless steel wire inserted through longitudinally drilled holes The group "Other Complications' included five patients Two of these got paralysis of the peronaeus which became permanent in one Suture migration was found in two patients Finally, in one patient there was a lengthening of the quadriceps tendon after total excision of the patella on re operation shortening of the tendon was performed

In none of the cases severe infection of the joint set in No cases of deep thrombosis nor thrombo embolism were diagnosed

Re-operations

22 patients (5%) were re operated on (Table 14)

Release of adhesions was performed in eleven cases If the mobility was considerably impaired the patella was mobilized during complete relaxation of the muscles In no case was this manipulation carried out earlier than two months after the trauma A sharp hook was inserted percutaneously at the basis

Table 13 Complications in 19 out of 416 patients with fracture of the patella

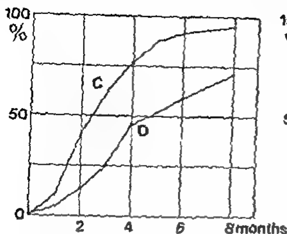

Fig 14

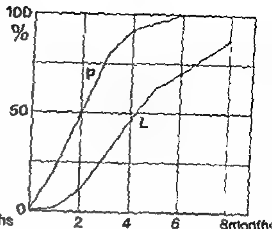

Fig 15

Fig 14 Cumulative *distribution graphs showing* period of sick leave after closed and open fracture of the *patella* Concomitant *injuries* are *included* (*C=closed* fracture, *O—open* fracture)

Fig 15 Cumulative distribution graphs showing period of sick leave in preserved and lost function of the quadriceps in fracture of the patella *Open* fractures and concomitant injuries are excluded (P=preserved quadriceps *function*, L=lost quadriceps function)

of the patella, lifting the patella slightly By pressing *the thumb* against the patella it was carefully worked loose Small movements from side to side were also *brought* about By this careful *manipulation* it was possible to avoid breaking *forces of the* fracture line or tens

group at Other Re *operations*' *the one* mentioned above, on whom a shortening of the quadriceps tendon was *performed*, two in whom sutural *granulomas* were extirpated, *and one* on whom an exploratory arthrotomy was *done in a late phase* because of diffuse *joint* pain In this case there was a 'slight defect' corresponding to the fracture

Sick-leave

Of 416 *patients* 306 *received* sickness *benefit* The period of sick leave also depended on factors *other than the fracture There* was no difference between *the* sexes nor between the *occupations in the length* of time of sick leave *After* open fracture the median *period of* sick leave was twice as *long as* that after closed (Fig 14) If the extensor function was preserved indicating *a minor* injury to the lateral expansions, half the number *of* patients was discharged after two months (Fig 15) If there was loss of active extension, four months elapsed before half the number of patients had recovered

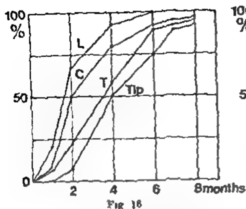

Fig 16

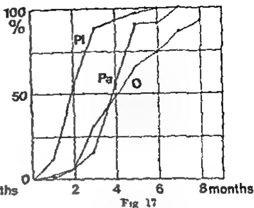

Fig 17

Fig 16 Cumulative distribution graphs showing period of sick leave for different types of patellar fracture Open fractures and concomitant injuries are excluded (L=longitudinal lateral fractures C=comminuted fractures T=transverse fractures with two large fragments Tip=transverse fractures with a split lower pole)

Fig 17 Cumulative distribution graphs showing period of sick leave with different methods of treatment in patellar fractures Open fractures and concomitant injuries are excluded (Pl=plaster cast—non-operative treatment Pa=partial patellectomy O=osteosynthesis)

Longitudinal lateral fracture (as well as longitudinal medial apical and basal fracture) resulted in shorter periods of sick leave as compared with other types of fracture (Fig 16)

Of the patients with a longitudinal lateral fracture 68 per cent were discharged after two months as restored but of those who had a transverse fracture with two large fragments only 22 per cent

The median period of sick leave for patients with a fracture not requiring surgical treatment was half of that required for patients with a fracture treated surgically (Fig 17)

After four months 91 per cent of the non surgically treated patients immobilized in a plaster cast had returned to work but only 49 per cent of those on which osteosynthesis had been performed The median period of sick leave was slightly shorter after partial patellectomy than after osteosynthesis

Certificate of disablement

After the treatment was terminated 19 patients received a certificate of disablement Two of these had concomitant injuries Of the remaining 17 patients five were granted lifelong compensation equivalent to a reduced capacity for work by 10-25 per cent Temporary compensation was granted to two patients The reduced capacity for work in the remaining ten cases was not found to exceed 10 per cent

CHAPTER IV

FOLLOW—UP STUDY

Case series

The follow up study was carried out during the period 1970–1971 The time of observation varied from 5 to 12 years The mean time of observation was 8 9 years The follow up study included 321 subjects (327 fractures) constituting 91 per cent of those alive at the time of the investigation 63 subjects had died 32 subjects were impossible to reach for various reasons Of the 321 subjects 247 were thoroughly examined according to the method mentioned below A further 25 subjects, most of whom were elderly were examined in nursing homes homes for the aged or in their own homes but were not radiographically examined The remaining 49 answered questionnaires but were not examined Of these 49 subjects, 21 were asked to come for examination more than four times but refused 22 lived more than 50 km from the hospital and a further six had died before the clinical investigation was terminated

From the time of injury to the time of the follow up 16 subjects sustained diseases and injuries in the same extremity earlier injured Of these eleven sustained a fracture of the femoral neck two other kinds of fracture and three injury of the meniscus Four subjects were struck by diseases and injuries in the other leg Two of these sustained a fracture of the femoral neck one a fracture of the ankle joint and one injury of the meniscus These 20 subjects are included in the series

One subject later sustained a new fracture of the patella of the same leg and was subjected to total patellectomy He was excluded from the series Two subjects later fractured the patella of the other leg These two latter fractures were not treated surgically The second fracture caused no discomfort They are included in the series but the other knee injured later was regarded as uninjured

When checking the series it was found that of the six subjects who had sustained bilateral fractures of the patella four had one slightly and one severely injured knee the latter of which only had been surgically treated one subject was non surgically treated bilaterally and the remaining was operated on both sides The condition of the latter subject at the follow up

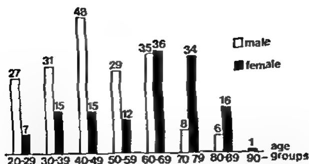

Fig 18 Distribution of age and sex among 320 subjects with fracture of the patella at the follow up study

was affected by the sequelae of a cerebral insult One knee of the two latter subjects and the slightly injured knee of the other four will in the following be regarded as uninjured The percentage of the poor results in the final report will not be affected by this exclusion

In the continued report of subjective symptoms the series includes 320 subjects The objective and radiographic findings are based on 271 and 246 subjects respectively

The distribution of the patients followed up with regard to age and sex is indicated in Fig 18

The mean age of the subjects followed up was 53 years, i e for 184 males 47 years and for 136 females 61 years The youngest subject was 21 years and the oldest 96 years of age

The distribution of non operative and operative treatment among various age groups of males and females in the follow up study is stated in Fig 19 Methods of treatment of various types of fracture are specified in Table 15

Methods

A questionnaire was sent to the subjects in which they were asked to state the following symptoms and active function as conceived before and after the injury pain swelling stiffness unsteadiness limping use of stick capability for walks mounting stairs running and sports Furthermore, they mentioned further sick leave because of the same injury change of occupation life annuity, and whether they believed that the injury had caused permanent disability

At the clinical examination between six and twelve months later the questionnaire was verbally discussed The consensus of the verbal and written answers was satisfactory and consequently it was believed that the subjects whose condition was assessed merely on the basis of the questionnaire, had given an adequate account of their condition

CHAPTER IV

FOLLOW—UP STUDY

Case series

The follow up study was carried out during the period 1970–1971 The time of observation varied from 5 to 12 years The mean time of observation was 8 9 years The follow up study included 321 subjects (327 fractures), constituting 91 per cent of those alive at the time of the investigation 63 subjects had died 32 subjects were *impossible to reach for various reasons Of the 321* subjects, 247 were thoroughly examined according to the method mentioned below A further 25 subjects, most of whom were elderly, were examined in nursing homes homes for the aged, or in their own homes, but were not radiographically examined The remaining 49 answered questionnaires, but were not examined Of these 49 subjects, 21 were asked to come for examination more than four times but refused, 22 lived more than 50 km from the hospital and a further six had died before the clinical investigation was terminated

From the time of injury to the time of the follow up, 16 subjects sustained diseases and injuries in the same extremity earlier injured Of these eleven sustained a fracture of the femoral neck, two other kinds of fracture and three injury of the meniscus Four subjects were struck by diseases and injuries in the other leg Two of these sustained a fracture of the femoral neck, one a fracture of the ankle joint and one injury of the meniscus These 20 subjects are included in the series

One subject later sustained a new fracture of the patella of the same leg and was *subjected to total patellectomy He was excluded from the series* Two subjects later fractured the patella of the other leg These two latter fractures were not treated surgically The second fracture caused no discomfort They *are included in the series, but the other knee injured* later was regarded as uninjured

When checking the series it was found that of the six subjects who had sustained bilateral fractures of the patella four had one slightly, and one severely, injured knee the latter of which only had been surgically treated one subject was non-surgically treated bilaterally and the remaining was operated on both sides The condition of the latter subject at the follow up

The nature and degree of pain and the subjectively experienced impairment of function was assessed on the basis of verbal and/or written questioning. Pain and ache were classified according to the following:

1. Temporary ache, e.g. with atmospheric changes or in kneeling posture
2. Ache when starting to walk or in connection with a lengthy position, e.g. in a squatting posture
3. Ache in connection with exertions
4. Ache caused by all activities
5. Pain at rest

In analyzing the impairment of function, consideration was taken to the age of the subject. An age limit of 60 years was selected and the functions included were scored (Table 16).

At the clinical examination, walking on a level surface as well as the capability of mounting and descending stairs were assessed. Extension defect and range of mobility of the knee joints were measured with an angle gauge. The maximal circumference of the calf, the circumference on a level with the patella and the circumference of the thigh 15 cm proximally to the medial interarticular space were measured on both legs.

Methods of measuring the extension force of the knee have been elaborated by Clarke *et al.* (1950). He suggests a sitting posture with the knee joint

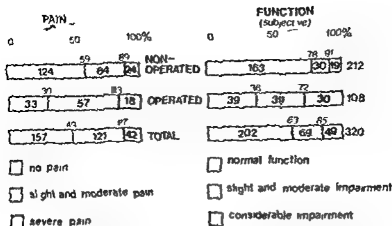

Fig 20 Subjective symptoms after non operative and operative treatment of fracture of the patella (The figures refer to percentage and number of subjects)

Results

Subjective Symptoms (320 subjects)

When the treatment was ended 78 subjects (24%) did not consider themselves to be fully recovered At a later date 44 (14%) came for consultation because of discomfort which could depend upon the injury An operation was performed on eight of these At the time of the questioning 225 (70%) were satisfied

The pain in the injured knee was considered as slight if it occurred in connection with kneeling or atmospheric changes as moderate when *starting to walk* and as the result of a lengthy squatting posture or during exertions The pain was *regarded* as severe if it persisted at rest and/or in all activities It was found that 157 subjects (49%) had no pain and 63 (20%) *had slight* pain Moderate pain was noted in 58 (18%) and severe in 42 (13%) *subjects*

The subjectively experienced impairment of function was considered slight if the corresponding score did not exceed 2 points The impairment of function was moderate if the score *exceeded 2 but not* 4 and 6 points respectively If the score was higher the *impairment* of function was classified as considerable No abnormality of the function was stated by 202 subjects (63%) Slight impairment of function was found in 51 (16%), moderate in 18 (6%) and considerable in 49 (15%) subjects

Subjective symptoms after non surgical and surgical treatment are indicated in Fig 20

None of the 49 subjects who merely answered the questionnaires had severe

flexed through 45 degrees Tornvall (1963) and Backlund & Nordgren (1968) measured the force with the subject in a sitting posture and the knee joint flexed through 90 degrees The mean value of the subjects aged 20–28 years was in the Tornvall series 50 kgf on the right and 47 kgf on the left side In medical students of the same age Backlund & Nordgren found 65 kgf on the right and 64 kgf on the left side

The force of the extensor muscles was measured in a special chair designed by Hook & Tornvall (1969) and equipped with a strain gauge dynamometer for measuring isometric power muscles The knee was flexed through 90 degrees The maximal force was recorded—often after several attempts the last value obtained being lower than the highest—and a percentage of the reduction of force was calculated on the force of the uninjured leg Measurements of the force of the knee extension was made with the assistance of Ewa Landegren, laboratory assistant Dept of Medical Rehabilitation II Sahlgren s hospital In cases when the subjects were examined elsewhere than in the hospital Zadig a dynamometer was employed (Zadig 1963)

Enlargement of the patella and its mobility was recorded as well as tenderness across the patella and crepitations in the knee joint

Radiographs were taken of both knee joints including frontal lateral and axial projections on the injured side two oblique projections were taken as well For loading the patellofemoral joint while the axial projection was taken, the subject was standing with the patella to be examined resting against a support mounted on a special examining stand and with the knee in a semi flexed position (Ahlback 1968) Other exposures were taken with the subject in a recumbent position (Ass Professor Sven Scheller planned the radiographic examination which was carried out by assistants at The Roentgen Department I Sahlgren s hospital Recording and assessment of the radiographic findings were performed by the author in conjunction with Ass Professor Scheller)

Appraisal of the consolidation of the fracture fibrous union and pseudarthrosis was included in the radiographic analysis Cerclage breakage was recorded as well as articular surface steps enlargement of the patella calcium bodies and bone resembling tissue in the surrounding area and formation and development of osteoarthrosis For the estimation of osteoarthrosis the most important factors were changes of the structure—deformation of articular surfaces presence of cysts and subchondral sclerosis—and a reduced joint space The presence of osteophytes was not sufficient evidence for osteoarthrosis to be diagnosed A source of error could exist as the femorotibial joint—as opposed to the patellofemoral joint—was not examined during weight bearing of the knee Osteoarthrosis was recorded and classified according to Kellgren & Lawrence (1957) and Kellgren (1963)

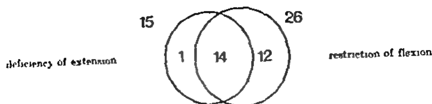

Fig 23 Restricted range of mobility in 27 subjects after patellar fracture

could be measured The range of mobility of the injured knee was normal in 244 subjects (90%) Restricted range of mobility was found in 27 subjects (10%) Deficiency of extension was recorded in 15 subjects (6%) Eight of these had moderate and seven considerable deficiency The flexion was restricted in 26 subjects (10%) Out of these 14 had moderate, and 12 considerable, restriction Both the deficiency of extension and the bending capacity to a flexed position of less than 120 degrees were recorded in 14 subjects (Fig 23)

Out of 27 subjects with restricted range of mobility, 21 (78%) were older than 60 years of age Operation had been performed on 16 subjects (60%) The median period of immobilization in plaster, 6 5 weeks, was exceeded in 6 subjects (38%) who were surgically treated

The circumference of the thighs was regarded as equal if the difference in the values measured was nil or less than 1 cm If the circumference of the thigh was reduced by at least 1 cm, atrophy of the quadriceps musculature was assumed Atrophy was assessed as moderate if the reduction was less than 2 cm and considerable if the reduction was at least 2 cm The circumference of the thighs was equal in 185 subjects (68%) Atrophy of the injured side was moderate in 38 (14%) and considerable in 27 subjects (10%) The circumference of the thigh of the injured side was increased in 21 subjects (8%)

The extension force of the knees was regarded as equal if the same value, including a decrease or increase of 10 per cent was obtained for both sides The extension force of the injured side was considered to be reduced if the reduction was more than 10 per cent and to be augmented if the increase was more than 10 per cent The reduction of force was classified as moderate if the reduction was less than 30 per cent and considerable if the reduction was at least 30 per cent Equal force was measured in 150 subjects (55%) Moderate reduction of force was noted in 64 (24%) and considerable in 35 subjects (13%) In 22 subjects (8%) the force of the extensor apparatus of the injured knee was increased

Only in exceptional cases did the force of the extensors exceed 80 kg The force of the extensors in the healthy knee varied with age and sex, as shown

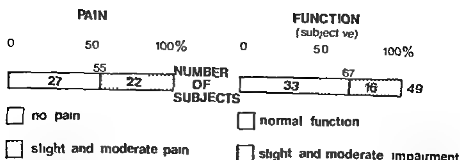

Fig 21 Subjective symptoms of 49 subjects who merely filled up the questionnaires

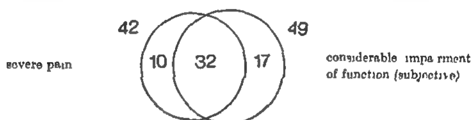

Fig 22 Severe pain and/or subjectively experienced considerable impairment of function in 59 subjects after fracture of the patella

pain or subjectively experienced considerable impairment of function (Fig 21)

Both severe pain and subjectively experienced considerable impairment of function were stated by 32 subjects (Fig 22)

The occupation of 243 subjects (76%) was the same or similar to that before the injury The conditions of living of 61 subjects (19%) irrespective of the injury had changed Most of these had received their old age pension 16 subjects (5%) had received a disablement pension or had changed over to lighter work owing to the injury Of these eight had temporary or lifelong compensation

Objective Signs (271 subjects)

The range of mobility of the injured knee was considered as normal if there was no deficiency of extension and if the knee could be flexed to at least 120 degrees It was considered as restricted if there was deficiency of extension and/or the bending capacity to a flexed position of less than 120 degrees could be measured The restriction was regarded as moderate if the deficiency of extension was less than or 10 degrees and/or the bending capacity could be measured to a flexed position of less than 120 degrees but more than 90 degrees It was regarded as considerable if the deficiency of extension exceeded 10 degrees and/or the bending capacity to a flexed position of 90 degrees or less

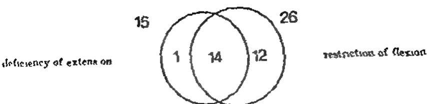

Fig 23 Restricted range of mobility in 27 subjects after patellar fracture

could be measured The range of mobility of the injured knee was normal in 244 subjects (90%) Restricted range of mobility was found in 27 subjects (10%) Deficiency of extension was recorded in 15 subjects (6%) Eight of these had moderate and seven considerable deficiency The flexion was restricted in 26 subjects (10%) Out of these 14 had moderate, and 12 considerable, restriction Both the deficiency of extension and the bending capacity to a flexed position of less than 120 degrees were recorded in 14 subjects (Fig 23)

Out of 27 subjects with restricted range of mobility, 21 (78%) were older than 60 years of age Operation had been performed on 16 subjects (60%) The median period of immobilization in plaster, 6 5 weeks was exceeded in 6 subjects (38%) who were surgically treated

The circumference of the thighs was regarded as equal if the difference in the values measured was nil or less than 1 cm If the circumference of the thigh was reduced by at least 1 cm atrophy of the quadriceps musculature was assumed Atrophy was assessed as moderate if the reduction was less than 2 cm and considerable if the reduction was at least 2 cm The circumference of the thighs was equal in 185 subjects (68%) Atrophy of the injured side was moderate in 38 (14%) and considerable in 27 subjects (10%) The circumference of the thigh of the injured side was increased in 21 subjects (8%)

The extension force of the knees was regarded as equal if the same value including a decrease or increase of 10 per cent was obtained for both sides The extension force of the injured side was considered to be reduced if the reduction was more than 10 per cent and to be augmented if the increase was more than 10 per cent The reduction of force was classified as moderate if the reduction was less than 30 per cent and considerable if the reduction was at least 30 per cent Equal force was measured in 150 subjects (55%) Moderate reduction of force was noted in 64 (24%) and considerable in 35 subjects (13%) In 22 subjects (8%) the force of the extensor apparatus of the injured knee was increased

Only in exceptional cases did the force of the extensors exceed 80 kg The force of the extensors in the healthy knee varied with age and sex, as shown

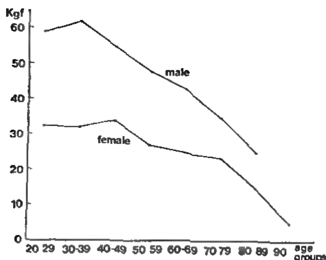

Fig 24 Mean values of the force of the extensors in the knee of the uninjured side of 271 subjects

in Fig 24, in which the mean values are given for males and females in the various age groups

The rate of considerable *reduction of extension force was the same for subjects* younger and older than 60 years of age Considerable reduction of force was found in 20 (23%) of 88 subjects, whose injury caused loss of active extension, and in 6 (5%) of 114 subjects whose capability of extension was preserved despite the injury *Considerable reduction of force was found in* 19 (23%) subjects with the fragments of fracture dislocated at least 4 mm, and in 16 (8%) with a diastasis less than 4 mm ($p<0\ 01$) Considerable reduction of force was found in 23 (26%) operated and 12 (7%) non operated subjects ($p<0\ 01$) *Out of the 23 subjects operated upon,* 16 were subjected to osteosynthesis, three to partial patellectomy and four to total patellectomy (26%, 13%, and 100% of the respective follow up series)

With an equally large circumference of the thighs great deviations in the extension force could be obtained When the circumference of both thighs was the same, the force measured in one subject could be increased by 20 per cent in the injured leg and in another reduced by 60 per cent The extension force was reduced in 77 (42%) of the 185 subjects in whom no atrophy was diagnosed On the other hand, there was no subject who had considerable atrophy and increased extension force in the same leg

The extension force was reduced in 25 (93%) of the 27 subjects who had restricted range of mobility of the injured knee

Fig 25 Longitudinal lateral fracture of the patella (A) treated with immobilization in plaster (B) shows fibrous union six years later (The late result was good)

Radiographic Findings (246 subjects)

25 subjects were clinically but not radiographically examined 19 were older than 60 years 22 were not inconvenienced by the knee injury, whilst three maintained that they had persisting disability owing to the injury Four elderly subjects who were free from symptoms had restricted range of mobility of the injured knee joint The circumference of the thighs was equal in all the 25 subjects Six subjects, three of whom were free from symptoms had reduced extension force of the injured knee

Union of the fracture fibrous union pseudarthrosis articular surface steps, and enlargement of the patella could be established by radiographic evidence in all the subjects except four on whom total patellectomy had been performed In 221 subjects (91%) the fracture had united

Fibrous union was established in 15 subjects (6%) Fig 25 Out of these, twelve had a longitudinal lateral fracture (Table 17) All 15 subjects were treated non operatively

Pseudarthrosis was established in 6 subjects (3%) The fact that they had pseudarthrosis was unknown to all of them Four were treated non operatively and two operatively (Table 17)

Table 17 Distribution of various types of fracture among 242 radiographically examined subjects having had patellar fractures, ending in fibrous union, pseudarthrosis and articular surface steps The figures in brackets indicate operatively treated cases

Radiographic findings					L	M			Total
Fibrous union	1			2	12				15 (6%)
Pseudarthrosis		1		1 (1)	1	2 (1)		1	[illegible] (3%)
Articular surface step ≥1 mm	7 (6)	4 (1)	10 (9)	6 (2)	7	1	1	4	40 (17%)

D

Fig 26 Comminuted fracture of the patella (A B) treated non operatively Six years later the patella was enlarged (C) compared with the opposite side (D) (The late result was excellent)

Out of the radiographically examined subjects, 51 were operatively treated by application of a metal wire In 46 cases the wire was intact, but in five it had broken in one or two places

A step in the articular surface of the patella of 1 mm or more was established in 40 subjects (17%) Table 17 Out of these 22 were not and 18 were subjected to surgery In 15 cases osteosynthesis was performed with a stainless steel wire inserted through longitudinally drilled holes

Enlargement of the patella was considered to exist if an increase of width of at least ½ cm could be measured on the radiograph (Fig 26) 39 (17%) had

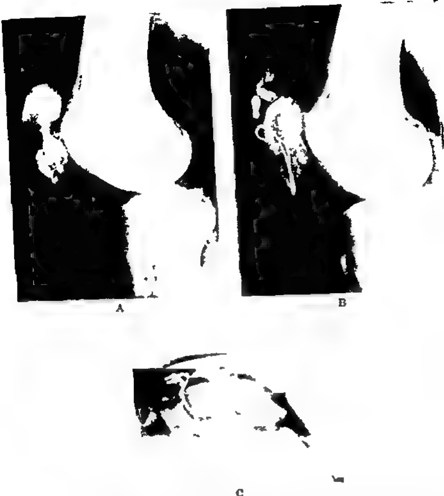

Fig 27 Transverse fracture of the patella with a split lower pole (A) treated with osteosynthesis with a metal wire through longitudinally drilled holes B and C, seven years later show bone resembling tissue in the surroundings of the patella, and articular surface step (The late result was poor)

enlargement of the patella of the injured side Out of these, 22 were non operatively and 17 operatively treated, constituting 13 and 21 per cent of the respective follow up series Enlargement of the patella was established after both osteosynthesis and partial excision

Sometimes calcium bodies in the surroundings of the patella were visible on the radiograph and pretty frequently bone-resembling tissue could be seen in the patellar ligament and the quadriceps tendon (Fig 27) These kinds

Fig 30 Osteoarthrosis of the injured knee, as well as of the patellofemoral joint of the opposite side at the follow up examination, and osteoarthrosis of the injured knee at the time of injury

femoral and and femorotibial joints of the same knee and, furthermore, develop bilaterally (Ahlback 1969) and as osteoarthrosis had been diagnosed in the primary series a diagram could be traced (Fig 30) showing the cases in which it could be assumed that the osteoarthrotic changes in the patellofemoral joint of the injured side had developed as a result of the injury There remained ten cases as stated in the diagram

However when patellofemoral osteoarthrosis was observed on the injured side it was also possible to establish whether the osteoarthrotic changes had become increased in comparison with the time of injury and with the opposite side This type of progressive osteoarthrosis was diagnosed in 24 subjects (10%), none of whom had osteoarthrosis in the femorotibial joint of the injured side

Osteoarthrosis—irrespective of the genesis and the location—depended on the age of the subjects at the follow up examination Osteoarthrosis of the injured knee was found in 42 (39%) of those over 60 years of age, and in 29 (21%) of those under ($p<0.01$) Osteoarthrosis of the knee occurred twice as often in females as in males Osteoarthrosis of the injured patellofemoral joint was diagnosed in 26 subjects (28%) who were injured in a traffic accident or

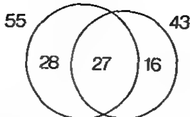

Fig 28 Osteoarthrosis of the injured knee of 71 subjects after patellar fracture

of changes were present in 67 subjects (27%) Out of these 56 were surgically treated The radiographic examination revealed these changes in almost all of those who had sustained partial or total excision of the patella

Osteoarthrotic changes were not diagnosed on the basis of slight formation of osteophytes and a normal height of the joint space without changes in the structure of the articular surface Slight osteoarthrosis was established if the formation of osteophytes was moderate and the joint space was slightly reduced with or without structural changes Moderate osteoarthrosis was present when the formation of osteophytes was moderate or pronounced the height of the joint space was moderately reduced and structural changes such as deformation of the articular surfaces and subchondral sclerosis were moderate Considerable osteoarthrosis was diagnosed when the formation of osteophytes and the reduction of the joint space were pronounced with a definite deformation of the articular surfaces with sclerosis and formation of cysts in the subchondral bone

Osteoarthrotic changes in the injured patellofemoral joint were observed in 55 subjects (22%) Out of these 33 had slight changes 15 moderate and seven considerable Osteoarthrotic changes in the femorotibial joint of the injured side were established in 43 subjects (18%) Out of these 28 had slight changes eleven moderate and four considerable The number of subjects with osteoarthrosis of the injured knee totalled 71 (29%) which is illustrated in *Fig 28*

In the patellofemoral joint of the opposite side osteoarthrotic changes were observed in 19 subjects (8%) Out of these seven had slight changes eight moderate and four considerable In the femorotibial joint of the opposite side osteoarthrotic changes were observed in 23 subjects (9%) Out of these 16 had slight changes six moderate and one considerable The total number of subjects with osteoarthrosis of the opposite side was 27 (11%) as demonstrated in Fig 29

Radiographs taken at the time of injury revealed osteoarthrotic changes in the injured knee joint in 35 subjects (9%)

As degenerative osteoarthrosis may occur simultaneously in both the patello

Table 18 Subjective symptoms correlated with various objective signs

Subjective symptoms	Objective signs				
Pain	Restricted range of mobility	Considerable reduction of force	Fibrous union and pseudarthrosis	Articular surface step ≧1 mm	Osteoarthrosis
No pain	7 (26%)	6 (17%)	10 (48%)	12 (30%)	19 (27%)
Slight	3 (11%)	4 (11%)	3 (14%)	9 (22%)	16 (22%)
Moderate	3 (11%)	6 (17%)	6 (29%)	10 (25%)	8 (11%)
Severe	14 (52%)	19 (55%)	2 (9%)	9 (23%)	28 (40%)
Total	27 (100%)	35 (100%)	21 (100%)	40 (100%)	71 (100%)

Out of the 27 subjects with a restricted range of mobility, 22 (82%) had osteoarthrosis at the primary or the follow up radiographic examination Out of the 35 subjects with a considerable reduction of force 21 (60%) had osteoarthrosis at the primary or the follow up radiographic examination

Classification of results

The result was considered *excellent* if the subject was free from discomfort without pain or subjectively experienced impairment of function, with a normal *range of mobility of the knee joint and with equal force in the extensor apparatus of both knees* The result was considered *poor* if the injury alone could be assumed to be the cause of pain at rest and/or pain during all kinds of activity Furthermore the result was regarded as poor if the injury alone could be assumed to be the cause of at least two of the following three symptoms and signs

1 Subjectively experienced impairment of function corresponding to a score exceeding 4 and 6 points respectively
2 Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less
3 Reduction of force of the extensor apparatus of the knee exceeding 30 per cent of the force of the uninjured knee

In all the other cases the result was considered *good* Subjects with a good result formed a heterogeneous group In this group were included in addition to those with a good result on account of the injury, also those with a poor result that was not ascribable to the injury but instead probably caused by

by fall from height, and 29 (19%) injured by other modes ($p>0.05$) After open fracture, osteoarthrosis of the injured patellofemoral joint was observed in 9 subjects (60%) and after closed fracture in 46 subjects (20%) ($p<0.01$) After comminuted fracture osteoarthrosis of the injured patellofemoral joint was diagnosed in 17 subjects (42%), and after other types of fracture in 38 (19%) ($p<0.01$) Osteoarthrosis of the injured patellofemoral joint occurred twice as often after operative as after non operative treatment (35% and 16% of the respective follow up series) ($p<0.01$) Osteoarthrosis of the femorotibial joint of the injured side occurred just as frequently after operative as after non operative treatment The frequency of osteoarthrosis was as large after osteosynthesis as after partial patellectomy (32% and 35% of the respective follow up series) All four subjects who were radiographically examined after total patellectomy had osteoarthrotic changes in the femoral component of the injured patellofemoral joint

There was no increase in the frequency of osteoarthrosis of the patello femoral joint because of fibrous union and pseudarthrosis (24% contra 22% in the other series)

Osteoarthrosis of the patellofemoral joint was found in 16 subjects (40%) with a step in the articular surface of the patella of 1 mm or more, and in 35 (17%) in the other series ($p<0.01$, four cases of total patellectomy excluded) Only seven of these 16 subjects had osteoarthrotic changes which could be assumed to have been formed or developed as a result of the injury Regarding only those with osteoarthrotic changes of the patellofemoral joint assumed to have been formed or developed as a result of the injury, the frequency of osteoarthrosis was insignificantly *higher in those with a step in* the articular surface of the patella of 1 mm or more as compared with the other series ($p>0.05$) Osteoarthrosis of the injured patellofemoral joint was insignificantly higher when there was enlargement of the patella (28% contra 22% in the other series after excluding the cases of total patellectomy) ($p>0.05$) *Osteoarthrosis of the injured knee was established in* 28 (42%) of the 67 subjects who had calcium bodies and bone resembling tissue in the surrounding areas of the patella and 43 (24%) in the other series ($p<0.01$)

Correlations

Pain connected with various objective signs is stated in Table 18

The subjects who had a restricted range of mobility and considerable reduction of force without pain were elderly subjects with osteoarthrosis, irrespective of the injury Half the number of subjects with fibrous union and pseudarthrosis felt no pain Some subjects with both osteoarthrosis and an articular surface step of 1 mm or more were free from pain

Table 18 Subjective symptoms correlated with various objective signs

Subjective symptoms	Objective signs				
Pain	Restricted range of mobility	Considerable reduction of force	Fibrous union and pseudarthrosis	Articular surface step ≧1 mm	Osteoarthrosis
No pain	7 (26%)	6 (17%)	10 (48%)	12 (30%)	19 (27%)
Slight	3 (11%)	4 (11%)	3 (14%)	9 (22%)	16 (22%)
Moderate	3 (11%)	6 (17%)	6 (29%)	10 (25%)	[illegible] (11%)
Severe	14 (52%)	19 (55%)	2 (9%)	[illegible] (23%)	28 (40%)
Total	27 (100%)	35 (100%)	21 (100%)	40 (100%)	71 (100%)

Out of the 27 subjects with a restricted range of mobility, 22 (82%) had osteoarthrosis at the primary or the follow up radiographic examination Out of the 35 subjects with a considerable reduction of force 21 (60%) had osteoarthrosis at the primary or the follow up radiographic examination

Classification of results

The result was considered *excellent* if the subject was free from discomfort without pain or subjectively experienced impairment of function with a normal range of mobility of the knee joint and with equal force in the extensor apparatus of both knees The result was considered *poor* if the injury alone could be assumed to be the cause of pain at rest and/or pain during all kinds of activity Furthermore the result was regarded as poor if the injury alone could be assumed to be the cause of at least two of the following three symptoms and signs

1 Subjectively experienced impairment of function corresponding to a score exceeding 4 and 6 points respectively
2 Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less
3 Reduction of force of the extensor apparatus of the knee exceeding 30 per cent of the force of the uninjured knee

In all the other cases the result was considered *good* Subjects with a good result formed a heterogeneous group In this group were included in addition to those with a good result on account of the injury, also those with a poor result that was not ascribable to the injury but instead probably caused by

another disease If it had been possible in these cases to assess the real result of the injury, one or other of the subjects might have been referred either to the group excellent or to the group poor results

Of those who merely answered questionnaires none were referred to the group poor results However it cannot be excluded that one or other might have been included in the group poor results if a complete examination had been carried out

Of those who were clinically examined, but not radiographically, two subjects were included in the poor results Possibly one of these or both could have been included in the group good results after complementary radiographic examinations which could have given evidence of osteoarthrosis not being connected with the injury

Pain at rest and/or pain during all kinds of activity was noted in 42 subjects In 16 of these the pain could depend on osteoarthrosis of the knee joint but with no relation to the injury A further seven had pain which could be caused by some other injury or disease The remaining 19 subjects were included in the group poor results owing to patellar fracture (Fig 31)

Impairment of function corresponding to a score exceeding 4 and 6 points respectively was subjectively experienced by 49 subjects In 26 of these the impairment of function could depend on osteoarthrosis some other disease or injury without any sure relation to the patellar fracture In the group poor results owing to patellar fracture the remaining 23 subjects were included (Fig 31)

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less was observed in 17 subjects Eight of these had a restricted range of mobility which could depend on some other injury or disease especially osteoarthrosis

Reduction of force of the extensor apparatus of the injured knee exceeding 30 per cent of the force of the uninjured knee was recorded in 35 subjects Out of these 16 subjects had reduced force which could depend on other disease or injury especially osteoarthrosis

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less and/or reduction of the force of the extensor apparatus of the knee exceeding 30 per cent was established in 46 subjects To the group poor results owing to fracture of the patella 22 of these were included (Fig 31)

A total of 73 subjects had one or several subjective symptoms or objective signs according to the criteria on which a poor result was based (Fig 31)

Excellent results were achieved in 145 (45%) and good results in 150 subjects (47%) The results were poor in 25 (8%) subjects The distribution of the results among males and females is indicated in Fig 32

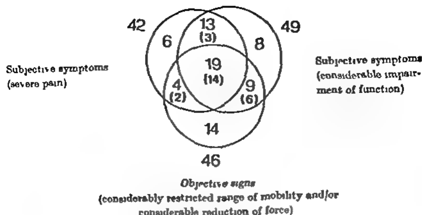

Fig 31 Subjective symptoms and objective signs of 73 subjects with a poor result in some respect The figures in brackets indicate the subjects who according to the classification, were considered to belong to the group poor results owing to patellar fracture

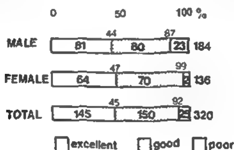

Fig 32 Late results of patellar fractures in males and females

There was no difference in the distribution of the results among those over 60 years of age as compared with those under (Fig 33)

After patellar fractures caused by traffic accidents or falls from height, poor results were more common than after patellar fractures caused by falls in the same plane and by direct blows ($p<0.01$) (Fig 34)

There were poor results of open fractures in 30 per cent and of closed fractures in 6 per cent ($p<0.01$) (Fig 35)

In subjects who had a concomitant injury, the result was more often poor as compared with those who had no other injury ($p<0.01$) (Fig 36)

The results of all types of transverse fracture and comminuted fractures

another disease If it had been possible in these cases to assess the real result of the injury, one or other of the subjects might have been referred either to the group excellent or to the group poor results

Of those who merely answered questionnaires, none were referred to the group poor results However, it cannot be excluded that one or other might have been included in the group poor results if a complete examination had been carried out

Of those who were clinically examined, but not radiographically, two subjects were included in the poor results Possibly one of these or both could have been included in the group good results after complementary radiographic examinations which could have given evidence of osteoarthrosis not being connected with the injury

Pain at rest and/or pain during all kinds of activity was noted in 42 subjects In 16 of these the pain could depend on osteoarthrosis of the knee joint but with no relation to the injury A further seven had pain which could be caused by some other injury or disease The remaining 19 subjects were included in the group poor results owing to patellar fracture (Fig 31)

Impairment of function corresponding to a score exceeding 4 and 6 points respectively was subjectively experienced by 49 subjects In 26 of these the impairment of function could depend on osteoarthrosis some other disease or injury without any sure relation to the patellar fracture In the group poor results owing to patellar fracture the remaining 23 subjects were included (Fig 31)

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less was observed in 17 subjects Eight of these had a restricted range of mobility which could depend on some other injury or disease especially osteoarthrosis

Reduction of force of the extensor apparatus of the injured knee exceeding 30 per cent of the force of the uninjured knee was recorded in 35 subjects Out of these 16 subjects had reduced force which could depend on other disease or injury especially osteoarthrosis

Deficiency of extension exceeding 10 degrees and/or bending capacity to a flexed position of 90 degrees or less and/or reduction of the force of the extensor apparatus of the knee exceeding 30 per cent was established in 46 subjects To the group poor results owing to fracture of the patella 22 of these were included (Fig 31)

A total of 73 subjects had one or several subjective symptoms or objective signs according to the criteria on which a poor result was based (Fig 31)

Excellent results were achieved in 145 (45%) and good results in 150 subjects (47%) The results were poor in 25 (8%) subjects The distribution of the results among males and females is indicated in Fig 32

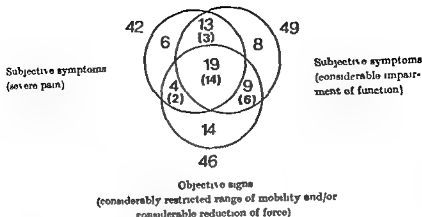

Fig 31 Subjective symptoms and objective signs of 73 subjects with a poor result in some respect The figures in brackets indicate the subjects who, according to the classification, were considered to belong to the group poor results owing to patellar fracture

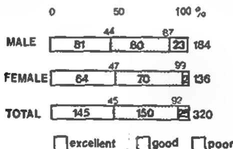

Fig 32 Late results of patellar fractures in males and females

There was no difference in the distribution of the results among those over 60 years of age as compared with those under (Fig 33)

After patellar fractures caused by traffic accidents or falls from height, poor results were more common than after patellar fractures caused by falls in the same plane and by direct blows ($p<0\ 01$) (Fig 34)

There were poor results of open fractures in 30 per cent and of closed fractures in 6 per cent ($p<0\ 01$) (Fig 35)

In subjects who had a concomitant injury, the result was more often poor as compared with those who had no other injury ($p<0\ 01$) (Fig 36)

The results of all types of transverse fracture and comminuted fractures

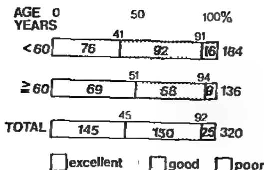

Fig 33 Late results of patellar fractures in various age groups

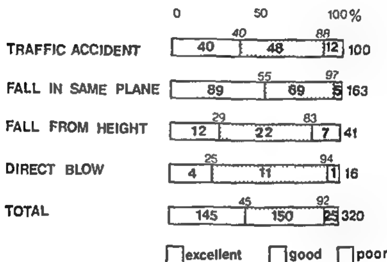

Fig 34 Late results of patellar fractures as related to the mode of injury

were equivalent (Fig 37) The result was poor in one subject who had sustained a longitudinal lateral fracture Also after longitudinal medial, apical and basal fractures, which generally were extra articularly situated, the result was poor only in exceptional cases (Fig 37)

When there was only slight separation of the fragments, the result was excellent or good in 98 per cent (Fig 38) If the diastasis was considerable, suggesting an extensive tear of the lateral expansions, the result was poor in 20 per cent

After non operative treatment the result was excellent in 118 subjects (56%), good in 92 (43%) and poor in 2 (1%) After operative treatment it was excellent in 27 subjects (25%), good in 58 (54%), and poor in 23 (21%), Fig 39

The results of various methods of operative treatment are stated in Fig 40

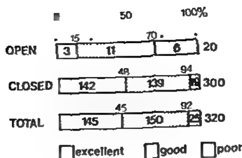

Fig 35 Late results of open and closed patellar fractures

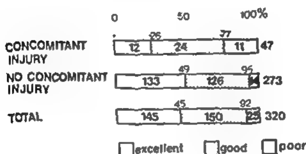

Fig 36 Late results of patellar fractures with and without concomitant injuries.

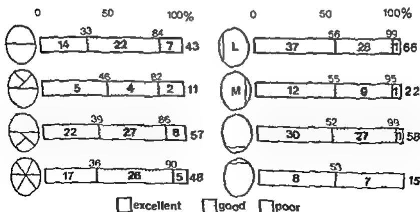

Fig 37 Late results of various types of patellar fracture

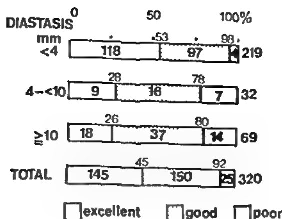

Fig 38. Late results of patellar fractures with regard to the separation between the fragments

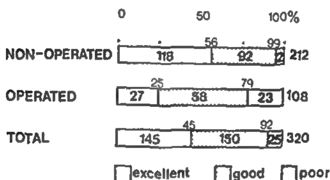

Fig 39 Late results of non operative and operative treatment of patellar fractures.

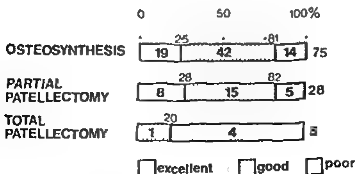

Fig 40 Late results of various methods of operative treatment for patellar fractures

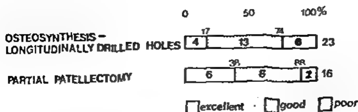

Fig 41 Late results of transverse patellar fractures with a split lower pole treated by means of either osteosynthesis or partial patellectomy

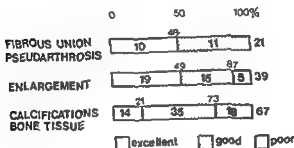

Fig 42 Late results of fibrous union and pseudarthrosis of enlargement of the patella and of presence of calcium bodies and bone resembling tissue in the surroundings after patellar fracture

After osteosynthesis and partial patellectomy poor results were equally frequent (19% and 18% of the respective follow up series) In none of the cases of total patellectomy was the result excellent

In transverse fractures with a split lower pole 23 subjects were treated with osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes and 16 with partial patellectomy (Fig 41) The results were poor in [redacted] subjects (26%) after osteosynthesis and in [redacted] (12%) after partial patellectomy ($p > 0.05$)

With fibrous union and pseudarthrosis 10 subjects (48%) had an excellent result 11 (52%) a good and none a poor (Fig 42)

Only one of 22 non operatively treated subjects who had a persisting step in the articular surface of the patella of 1 mm or more revealed at the follow up examination had a poor result the result was excellent in [redacted] (41%) and

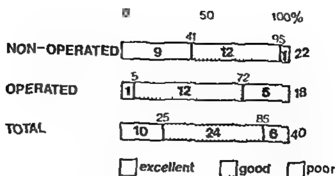

Fig 43 Late result in 40 subjects with a persisting step in the articular surface of the patella of 1 mm or more after patellar fracture

good in 12 subjects (54%), Fig 43 *Five subjects (28%) of those operatively* treated, with a persisting step in the articular surface of the patella of 1 mm or more, were referred to the group poor results, only one achieved an excellent result

The result of enlargement of the patella, radiographically verified, and of the presence of calcium bodies and bone resembling tissue in the surroundings, are indicated in Fig 42

All subjects referred to the group poor results, owing to patellar fracture, stated that they were not restored when the treatment terminated, and that the discomfort continued When the treatment was ended certificates of disablement were issued to 17 subjects owing to sequelae of the patellar *fracture, 16 of whom were followed up Five subjects,* in this investigation referred to the group poor results, were not considered by the insurance companies to have reduced capacity for work exceeding 10 per cent (Table 19)

Table 19 Late results of 16 subjects as classified by insurance companies with regard to compensation for reduced capacity for work after patellar fracture

CHAPTER V

DISCUSSION AND CONCLUSIONS

Series

Fracture of the patella strikes subjects of all ages The mean age in this series was 48 years which is higher than reported by other authors In conformity with Nummi (1971) the mean age of males was considerably lower as compared with females

The percentage of injured males was 57 which is less than stated in most other reports

Several authors state that fracture of the patella occurs in an increasing frequency as a result of traffic accidents In agreement with Schönbauer (1959) and Nummi the present series does not support this statement In males younger than 50 years of age traffic accidents however were the most common cause of patellar fracture The classification of different types of patellar fracture varies with the authors and comparisons are difficult to make The number of longitudinal lateral fractures was remarkably large probably depending on a careful radiographic examination and furthermore on the fact that the series similar to that of Nummi included ambulant cases Both these investigations show—as opposed to an earlier concept—that the longitudinal lateral fracture is a common type of patellar fracture In conformity with Smillie (1970) it was found that a number of different types of fracture may result from the same mode of injury From the appearance of the fracture, no sure conclusions could be drawn as to the modes of injury

The injury to the lateral expansions was of decisive importance for selecting the method of treatment With a diastasis of 4 mm or more the tear of the lateral expansions was so widespread that there was loss of active extension in most of the cases The operatively treated patients constituted 32 per cent of the entire series This group was of the same magnitude as that of Nummi (35%)

The post operative complications were few and of the same proportions as those reported by other authors (cf Nummi 5%) However it is remarkable that no cases of thrombosis or thrombo embolism were diagnosed

Some authors hold the opinion that several days should elapse after the

injury before applying a plaster cast In this series a plaster cast was applied immediately As a rule this did not involve any disadvantages However two patients contracted paralysis of the peroneus after the plaster was applied

Re operation was rarely necessary Only in exceptional cases (4 cases) was there reason to remove the metal wire Nummi reported 62 extirpations of the metal wire frequently done because of pain where the wire knot was tied The low frequency of extirpation of the metal wire in this series no doubt depended on the twined end of the wire having been recessed into the patella

Conclusive comparisons with regard to periods of sick leave and compensation for disablement between the various series are frequently difficult to make as the social and economical advantages vary with the diffent countries The periods of sick leave in this investigation were equivalent to those of Nummi after both non operative and various types of operative treatment

At the follow up study it was in conformity with other authors possible to establish that subjective symptoms occurred to a great extent after patellar fracture As the period of observation was almost nine years and the mean age at the follow up examination was 53 years it is necessary to bear in mind that there may be other reasons for the joint discomfort than the sequelae of patellar fracture

Restricted range of mobility was found mainly in elderly subjects and in those who had osteoarthrosis Contrary to Ehlert (1963) a long period of immobilization in plaster was not found to prevent the recovery of mobility at long sight

Measuring of the circumference of the thigh should be combined with recording of the force of the extensors of the knee in order to allow an adequate interpretation of the quadriceps function This especially applies when the circumference of both legs is equal in size The figures obtained possibly did not represent the maximal force which according to Clarke *et al* (1950) and Hallen & Lindahl (1967) is reached when the knee joint is flexed through 60–75 degrees The figures recorded were the same as those obtained from an equivalent age group by other Swedish authors

As other authors have pointed out the force of the extensors of the knee was often reduced after fracture of the patella and particularly after total patellectomy The force of the extensor apparatus of the knee is no doubt affected also by factors other than the reduced length of the lever (cf Stener 1969) e g painful hydrops of the joint (de Andrade Grant & Dixon 1965) and inflammatory changes (Tiselius 1969) It is possible that the force of extension after healing of the patellar fracture depends on the tear of the lateral expansions at the time of injury

The theory supported by several authors (cf Schonbauer 1955 J Bohler 1961 Nummi 1971) that steps in the articular surface of the patella provoke

osteoarthrosis, has not been realized in this investigation An increase in the frequency of osteoarthrosis of the patellofemoral joint, assumed to have been formed or developed as a result of the injury, was indeed recorded when there was a step of the articular surface amounting to 1 mm or more, but the difference in frequency was not significant Furthermore, quite a few subjects with a step in the articular surface of the patella experienced no pain

Thomson (1942) maintained that enlargement of the patella did not occur after partial patellectomy In this investigation, enlargement of the patella occurred after both partial patellectomy and osteosynthesis and, furthermore, after both non operative and operative treatment As opposed to Sorensen (1964) there was no increase in the frequency of osteoarthrosis with enlargement of the patella in this investigation

Many authors have pointed out that osteoarthrosis may set in after a joint lesion In this investigation, there were possibilities of establishing the development of osteoarthrosis which could be secondary to the injury, and of that which could depend on other circumstances

A rather high frequency of osteoarthrosis of a primary type could be expected as the higher age groups included many females (Hernborg 1969) The frequency of osteoarthrosis as reported in other series, is probably too high because no distinction has been made between primary and secondary osteoarthrosis Nummi agrees that his figures are too high Sorensen mentions that only in exceptional cases had he access to radiographs taken at the time of injury and, thus, was unable to assess development of osteoarthrosis Without doubt, however, osteoarthrosis may develop as a direct result of the injury In this series there was an increase in the frequency of osteoarthrosis after open fracture, comminuted fracture and operative treatment, whilst the choice of operation method seemed to be of secondary importance Some of the subjects with osteoarthrosis were free from pain

Poor results were recorded in 8 per cent of the entire series (25/320) In the group poor results, Fontaine *et al* (1965) included 10 per cent (8/78) Villiger (1965) 4 per cent (3/82), Detmar (1966) 7 per cent (7/104), Struck (1966) 6 per cent (5/82) and Nummi (1971) 8 per cent (32/391)

There was a distinct male predominance among those included in the poor results following patellar fracture On the other hand, the late results were equivalent with respect to age over and under 60 years The mode of injury and other circumstances connected with the trauma were essential Traffic injury and fall from height open fracture and concomitant injury were factors which contributed to a poor result

Excellent and good results of longitudinal, apical and basal fractures were achieved to a large extent In these fractures the injury to the lateral expansions was often slight This investigation does not support the opinion held,

for instance by de Palma (1954) that longitudinal lateral fractures should be treated surgically in order to avoid future discomfort Despite the fact that fibrous union was most common in longitudinal lateral fractures the frequency of poor results was low

Excellent good and poor results were recorded to the same extent in transverse types of fracture as in comminuted fractures The type of fracture seemed to be of secondary importance as compared with the injury to the lateral expansions

In conformity with other authors this series revealed to a great extent excellent and good results of the fractures to which non operative treatment was applicable In this series poor results were noted in 1 per cent (2/212) of fractures treated non operatively In the group poor after non operative treatment Fontaine *et al* included 5 per cent (1/20) Villiger 5 per cent (1/21) Detmar 11 per cent (3/27) Struck 4 per cent (2/51) and Nummi 4 per cent (10/236)

In the cases treated operatively the results were less satisfactory as expected Poor results in this series amounted to 21 per cent (23/108) The corresponding figures of poor results in other series are lower Fontaine *et al* reported 12 per cent (7/58) Villiger 3 per cent (2/61) Detmar 5 per cent (4/77) Struck 10 per cent (3/31) and Nummi 14 per cent (22/155)

However the results cannot simply be compared The late results of a joint lesion can be assumed to depend on other conditions than the injury and often the extent of consideration taken to this fact is not clearly expressed Furthermore the methods of analysis and the criteria vary with different authors

Excellent good and poor results were recorded to the same extent after methods used for restoration of normal anatomy and after partial patellectomy Too few patients were subjected to total patellectomy for any conclusions to be drawn as to the value of this method of operation The patients on whom total excision of the patella was performed all had open fractures The most common method of operation employed in attempting to restore the anatomy was stainless steel wire inserted through longitudinally drilled holes according to Payr It was used both for transverse and comminuted fractures Operative treatment of transverse fractures with a split lower pole could be performed either by osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes or by partial patellectomy In the follow up study there were 23 and 16 subjects respectively who had been operated on by the use of these methods Partial patellectomy tended to give better results of this particular type of fracture as compared to osteosynthesis but the groups of patients were small and the differences not significant

In no case of fibrous union and pseudarthrosis were the late results poor a fact experienced also by Nummi

A step in the articular surface of the patella of 1 mm or more did not affect the late results of non operatively treated cases Nor did a persistent step in the articular surface of the patella of 1 mm or more significantly increase the frequency of poor results of operatively treated cases This may imply that it is not essential to attain exact reposition and that a difference of level of 2–3 mm between the fragments can be accepted and treated non operatively, if there is no other indication of operation

Enlargement of the patella did not affect the late results Nor did the enlargement provoke osteoarthrosis and, consequently, this finding is of little clinical importance Calcium bodies in the surroundings of the patella, and bone resembling tissue in the quadriceps tendon and in the patellar ligament gave poor results, approximately to the extent expected in view of the fact that most of the patients had been treated by surgery The frequency of osteoarthrosis with these above mentioned changes, was also just as high as that obtained after operative treatment The clinical importance of these changes is probably insignificant

Finally, it is remarkable that all the subjects with a poor result pointed out that they were not restored at the end of the treatment and that the discomfort continued

Conclusions

Certain misgivings are involved with fracture of the patella inasmuch as persistent disability may result in the form of pain subjectively experienced reduction of function, restricted range of mobility, reduced force of extension of the knee and osteoarthrosis On the basis of a follow up study of 320 patients, subjected to patellar fracture, the following was found

1 The mechanism of injury and the severity of the trauma affect the late results of patellar fracture In traffic accidents and falls from height, and also in open fractures and concomitant injuries there will be a greater risk of a poor result

2 Various types of fracture may result from the same mode of injury A particular type of fracture is no true indication of the mode of injury Nor is it generally possible to give a sure statement of the prognosis on the basis of the type of fracture However, there is a good prognosis for longitudinal, apical and basal fractures, in all probability depending on the injury to the lateral expansions being slight in most of these fractures

3 The patient s capacity for extension of the knee, the separation and the difference of level between the fragments are factors to be borne in mind when deciding whether non operative or operative treatment shall follow When the extension capacity is preserved, the separation of fragments is

for instance, by de Palma (1954) that longitudinal lateral fractures should be treated surgically in order to avoid future discomfort Despite the fact that fibrous union was most common in longitudinal lateral fractures the frequency of poor results was low

Excellent, good and poor results were recorded to the same extent in transverse types of fracture as in comminuted fractures The type of fracture seemed to be of secondary importance as compared with the injury to the lateral expansions

In conformity with other authors, this series revealed to ■ great extent excellent and good results of the fractures to which non operative treatment was applicable In this series poor results were noted in 1 per cent (2/212) of fractures treated non operatively In the group poor, after non operative treatment, Fontaine *et al* included 5 per cent (1/20), Villiger 5 per cent (1/21), Detmar 11 per cent (3/27), Struck 4 per cent (2/51) and Nummi 4 per cent (10/236)

In the cases treated operatively, the results were less satisfactory, as expected Poor results in this series amounted to 21 per cent (23/108) The corresponding figures of poor results in other series are lower Fontaine *et al* reported 12 per cent (7/58), Villiger 3 per cent (2/61) Detmar 5 per cent (4/77) Struck 10 per cent (3/31) and Nummi 14 per cent (22/155)

However, the results cannot simply be compared The late results of a joint lesion can be assumed to depend on other conditions than the injury, and often the extent of consideration taken to this fact is not clearly expressed Furthermore the methods of analysis and the criteria vary with different authors

Excellent good, and poor results were recorded to the same extent after methods used for restoration of normal anatomy and after partial patellectomy Too few patients were subjected to total patellectomy for any conclusions to be drawn as to the value of this method of operation The patients on whom total excision of the patella was performed all had open fractures The most common method of operation employed in attempting to restore the anatomy was stainless steel wire inserted through longitudinally drilled holes according to Payr It was used both for transverse and comminuted fractures Operative treatment of transverse fractures with a split lower pole could be performed either by osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes or by partial patellectomy In the follow up study there were 23 and 16 subjects respectively who had been operated on by the use of these methods Partial patellectomy tended to give better results of this particular type of fracture as compared to osteosynthesis but the groups of patients were small and the differences not significant

In no case of fibrous union and pseudarthrosis were the late results poor, a fact experienced also by Nummi

Restoration of normal anatomy is recommended for transverse fractures with two large fragments and comminuted fractures when the articular surface can be restored

Repair of the quadriceps apparatus retaining one large fragment is recommended in transverse fractures with a split upper or lower pole and in comminuted fractures if the articular surface cannot be restored and there is a large fragment including more than half of the patella

Total excision of the patella never seems to be a treatment of choice but is recommended in exceptionally severe cases e g open comminuted fractures or when other methods of treatment have failed

Irrespective of the operation method selected it is essential that the tear of the lateral expansions be identified and that the anatomy be accurately restored

The post operative procedure is the same irrespective of the operation method selected Immobilization in a plaster cast with the knee flexed through 5 10 degrees during 6–7 weeks is indicated The patient should be instructed to practice active exercise of the quadriceps muscles (Svantesson 1971) When the quadriceps muscles can be contracted leg raising is instituted Weight bearing and mobilization on crutches as protecting support are permitted when the patient can lift his leg When the plaster cast has been discarded the patient should be instructed how to practice active exercises Primarily this includes i ometric and later also isotonic extension and flexion exercises—in the beginning without and later with increasing resistance The exercises should be carried out under the supervision of a physiotherapist

3–4 mm or less, and the difference of level is 2–3 mm or less, excellent and good late results can be expected after non operative treatment The prognosis is less good after operative than after non operative treatment, no doubt, owing to the more serious injury necessitating operative treatment The choice of operation method is probably of secondary importance as compared with the mode of injury and other circumstances involved with the trauma

4 After a joint lesion such as a fracture of the patella subjective symptoms and objective signs may depend—particularly with increasing age—on circumstances other than sequelae of the injury, especially osteoarthrosis

5 It is difficult to come to any definite conclusions when comparing between different series owing to the varying criteria used for classification However, after perusal of the literature on the subject and after study of this series *there has not been any reason to recommend the introduction of* another method of treatment, nor to advise against the use of any of the methods which were applied in this series

Suggestion of treatment

On the basis of the literature and this series the following is recommended

Non Operative Treatment

The patient's capacity for lifting his leg with the knee extended, the extent of separation and the difference of level between the fragments must be considered when deciding between non operative and operative treatment When the extension capacity of the knee is preserved the diastasis is 3–4 mm or less, *and the step in the articular surface is 2–3 mm or less* non operative treatment is advised If there is loss of active extension of the knee and the diastasis is less than 4 mm the patient should be hospitalized and the joint should be punctured, pending the development A severe tear of the lateral expansions involved with this diastasis is most unlikely

In non operative treatment immobilization in a plaster cast during four weeks is generally sufficient the time of which can be reduced in cases of longitudinal fracture The patient should be instructed to practice active exercise of the quadriceps muscles Weight bearing is permitted Crutches as protecting support are recommended

Operative Treatment

Loss of active extension of the knee and a diastasis of more than 3–4 mm and a step in the articular surface of the patella of more than 2–3 mm are indications for operation

bilized in a plaster cast, was two months, and of those operated on four months The median period of sick leave was insignificantly shorter after partial patellectomy than after osteosynthesis

Follow up examination was carried out 5–12 years after the injury The mean time of observation was 8 9 years The late results of 320 subjects—totalling 91 per cent of those alive at the time of the follow up—were reported A questionnaire was filled up A clinical examination was performed on 271 subjects Pain and subjectively experienced impairment of function were recorded as well as the range of mobility of the knee joint, the circumference of the thigh and the force of the extensors of the knee The radiographic examination of both knee joints in 246 subjects gave evidence of union, fibrous union, pseudarthrosis, cerclage breakage, step in articular surface, enlargement of the patella calcium bodies and bone resembling tissue in the surroundings, and formation and development of osteoarthrosis

70 per cent of the subjects were satisfied and stated that the injury had not caused persisting discomfort 59 per cent of the non operatively and 30 per cent of the operatively treated subjects felt no pain A normal function was subjectively experienced by 78 per cent of the non operatively and 36 per cent of the operatively treated subjects

Deficiency of extension of the knee was recorded in 6 per cent, and bending capacity to a flexed position of less than 120 degrees was noted in 10 per cent The circumference of the thigh of the injured leg was reduced in 24 per cent The extension force of the knee was reduced in 37 per cent Reduction of force occurred to a greater extent when the separation between the fragments measured 4 mm or more

Fibrous union was more often found in longitudinal lateral fractures than in other types of fracture, but caused no poor results Pseudarthrosis was recorded in 3 per cent and occurred after both non operative and operative treatment no case of poor results was noted A step in the articular surface of the patella of 1 mm or more was observed in 40 subjects (17%), half of whom were operated upon the majority according to the method of osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes There was possibly no relation between a step in the articular surface and formation and development of osteoarthrosis in the patellofemoral joint caused by the injury Enlargement of the patella as well as calcium bodies and bone resembling tissue in the patellar surroundings did not seem to be of clinical importance Formation and development of osteoarthrosis could result from the injury, but the occurrence of osteoarthrosis was often independent of the injury and was mainly seen in females in advanced ages

Excellent results were achieved in 45 per cent and good results in 47 per cent, while poor results were noted in 8 per cent There was a decided male

CHAPTER VI

SUMMARY

The series includes 416 patients who were radiographically examined in Gote borg during the period 1959–1964 because of injury to the knee and the diagnosis was a fresh fracture of the patella

57 per cent were males and 43 per cent females, the mean age was 42 and 54 years, respectively The maximum of frequency for males was reached between the ages of 30 and 39 years, and for females between 60 and 69 years

The most common mode of injury was a fall in the same plane (54%) the next common various types of traffic accidents (28%) In [illegible] per cent there was an open fracture and in 15 per cent a concomitant injury which in almost half of the cases involved the lower extremities

Transverse fractures were diagnosed in 34 per cent, comminuted in 16 per cent longitudinal lateral in 22 per cent and others including longitudinal medial, apical, and basal fractures in 28 per cent The different modes of injury exhibited a large variety of fractures 51 per cent of the fractures were non dislocated and in a total of 70 per cent the diastasis was less than 4 mm The step in the articular surface in this dislocation was nearly always less than 3 mm A diastasis of at least 4 mm was established in 30 per cent A loss of active function of the quadriceps muscles was found in 33 per cent

Non operative methods of treatment were considered advisable in preserved extension capacity of the knee diastasis less than 4 mm and a step in the articular surface less than 3 mm 287 fractures in 282 patients (68%) were treated non operatively usually with immobilization in a plaster cast during 3 5 weeks 135 fractures in 134 patients (32%) were subjected to surgery The most common method of operation was osteosynthesis with a stainless steel wire inserted through longitudinally drilled holes Partial patellectomy was the next common method of operation while total excision of the patella was performed only exceptionally All the methods of operation were followed by immobilization in plaster the median period of which was 6 5 weeks Complications occurred in [illegible] per cent Re operation was performed in 5 per cent The most common re operation was mobilization of the patella performed owing to restricted mobility of the knee joint after the plaster cast had been discarded

The median period of sick leave of non operatively treated patients immo

ACKNOWLEDGEMENTS

I wish to express my gratitude to

Professor Carl Hirsch, M D , who gave me the idea of penetrating this subject, and who has supported and encouraged me,

Professor Erik Moberg, M D , who kindly put the case records of his Clinic at my disposal and gave me valuable suggestions

Professor Bertil Stener, M D —under whose guidance I have carried out this investigation—for his personal interest and thorough criticism,

Ass Professor Sven Scheller, M D , for his appreciated co operation,

Mrs Lois Goldie Carlson who translated this paper,

Miss Margareta Apelskog and Mrs Mona Parmvik, who typed the manuscript,

Albee introduced the intraarticular arthrodesis of the hip in 1908. Until quite recently this method has maintained a prominent position in the surgical treatment of painful coxarthrosis (Rütt 1969). According to the literature, the chief advantage of arthrodesis over other methods is that it gives permanent relief from pain and instability. The operation has therefore traditionally been considered well indicated for people doing heavy work or whose occupation involves much walking and/or standing.

The aim of the operation in bilateral hip disease has commonly been to achieve, not only stability and freedom from pain in the more severely affected joint, but at the same time to retard or arrest progress of the disease in the less affected hip. The leg on the fused side was thus intended to be used for main support (Watson-Jones 1956, Francillon 1957, Wiberg 1959, Herbert 1960; Mach 1964; Verheugen and Navarre 1964; Becker 1969).

However, a fairly extensive search of the literature failed to reveal adequate studies of the support pattern following arthrodesis of the hip or of the fate of the (unoperated) mobile hip, compared with its preoperative condition in the two forms of coxarthrosis, the primary and secondary

This investigation attempts such a study of 125 cases who had 2 to 22 years previously undergone arthrodesis because of unilateral or bilateral coxarthrosis The investigation comprised a registration of the static support pattern, a comparative study of preoperative and follow-up radiograms of the mobile hip and a clinical examination. The following parameters were studied

a) the extent to which the fused hip was used for static support;

b) the incidence, rate and degree of radiographic deterioration of the mobile hip;

c) the incidence and severity of pain in the mobile hip and the limiting effect of pain on daily activities and working capacity.

I. INTRODUCTION

Albee introduced the intraarticular arthrodesis of the hip in 1908. Until quite recently this method has maintained a prominent position in the surgical treatment of painful coxarthrosis (Rütt 1969). According to the literature, the chief advantage of arthrodesis over other methods is that it gives permanent relief from pain and instability. The operation has therefore traditionally been considered well indicated for people doing heavy work or whose occupation involves much walking and/or standing.

The aim of the operation in bilateral hip disease has commonly been to achieve, not only stability and freedom from pain in the more severely affected joint, but at the same time to retard or arrest progress of the disease in the less affected hip. The leg on the fused side was thus intended to be used for main support (Watson-Jones 1956, Francillon 1957, Wiberg 1959, Herbert 1960; Mach 1964; Verheugen and Navarre 1964, Becker 1969).

However, a fairly extensive search of the literature failed to reveal adequate studies of the support pattern following arthrodesis of the hip or of the fate of the (unoperated) mobile hip, compared with its preoperative condition in the two forms of coxarthrosis, the primary and secondary.

This investigation attempts such a study of 125 cases who had 2 to 22 years previously undergone arthrodesis because of unilateral or bilateral coxarthrosis. The investigation comprised a registration of the static support pattern, a comparative study of preoperative and follow-up radiograms of the mobile hip and a clinical examination. The following parameters were studied

a) the extent to which the fused hip was used for static support;

b) the incidence, rate and degree of radiographic deterioration of the mobile hip;

c) the incidence and severity of pain in the mobile hip and the limiting effect of pain on daily activities and working capacity.

II MATERIAL AND METHODS

A Classification of Coxarthrosis

On the basis of preoperative radiograms of the hips, the cases were classified as unilateral or bilateral coxarthrosis Radiographic signs of osteophytes, narrowed joint space or structural changes, were used as criteria of coxarthrosis (Heripret, Danielsson and Dymling 1964). Distinction between primary and secondary coxarthrosis was based on the history and radiographic appearance

B Material

The source material comprised 336 cases treated at the Orthopaedic Departments of the Lund University Hospitals in Lund and Malmö. Arthrodesis because of coxarthrosis came into regular use in Lund in 1945 and in Malmö in 1952 All cases operated through 1965 were included in the source material It consisted of 195 females and 141 males, a ratio of 1 3/1 The average age at operation was 55 years the same for both sexes Over half of the cases were 50 to 65 years old at operation (Fig 1)

1 Base Material

Hospital records of 9 cases were missing or incomplete This reduced the number of cases to 327 (*Base Material*) on which adequate data were available From the records and radiographic descriptions of these cases it was found that at the time of operation 177 had unilateral and 150 bilateral coxarthrosis The distribution between primary and secondary coxarthrosis was 191 and 136 cases respectively

2 Selection of the Probands

Only cases filling the following requirements were accepted

a) the mobile hip must not have been rendered unfit for radiographic assessment by a high congenital dislocation or some intraarticular operation,

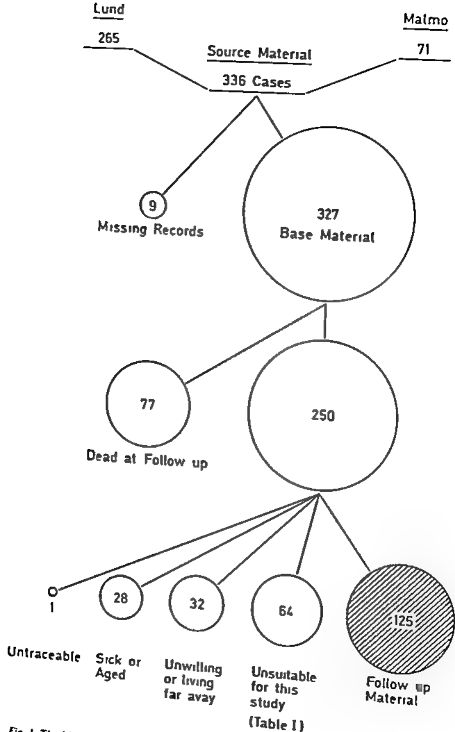

Fig 1 The Material

b) radiographic and/or clinical signs of firm union in the operated hip,

c) available preoperative radiograms of the mobile hip or adequate radiographic and clinical descriptions of the preoperative state,

d) availability of the case at the time of follow-up examination.

Potential probands were contacted by letter and/or telephone All those willing and able to participate were examined In all, 159 cases were examined but 34 of these failed to meet the above requirements (non-union 28; arthroplasty of mobile hip 4; high congenital dislocation of mobile hip 2). A further 30 were excluded because of similar findings in the records and radiograms (Table I).

Table I. Cases found unsuitable for follow-up

Cause	Number
Mobile Hip	
Arthroplasty or Resection	15
High Congenital Dislocation	3
Operated Hip	
Resection (Girdlestone)	4
Non-union	41
Femoral Amputation	1
Total	64

In 12 cases the radiograms obtained at follow-up were inconclusive, i. e. lacking in definite radiographic evidence of solid union. All these hips were free from pain and clinically firmly united. Although osseous union may not always have been complete, all 12 cases were accepted as probands.

Of 16 cases in which preoperative radiograms of the mobile hip were not available, 10 were free from signs of arthrosis at follow-up The remaining 6 had minimal changes, i. e. only slightly reduced joint space and/or marginal osteophytes. The interval between the operation and follow-up of these 6 cases was 15 to 22 years. It was therefore considered reasonably certain that these hips had been

normal at the time of operation. These cases were accepted as probands.

Four cases with bilateral disease at the time of operation were accepted as probands despite unavailability of preoperative radiograms of the mobile hip. The hospital records of all 4 cases contained adequate descriptions of the original radiograms.

3 Description of Probands

Seventy seven of the 125 probands were females and 48 males, a ratio of 1.6/1 At operation 75 probands had unilateral and 50 bilateral coxarthrosis, and 61 had primary and 64 secondary coxarthrosis in the hip that was fused

The distribution within the different subgroups of the material was largely the same in the Base Material as in the Follow-up Material (Fig 2) The only appreciable difference was a relative loss of males with primary coxarthrosis and a corresponding gain of females with secondary coxarthrosis

Of the 77 cases dead att follow-up, 42 were males Two thirds of the 77 cases had had primary coxarthrosis

a Unilateral Coxarthrosis

Of the 75 cases operated for unilateral coxarthrosis, 50 had secondary and 25 primary coxarthrosis. The diagnoses in the secondary cases are given in Table II. There were 53 females and 22 males.

c Age at Operation

More than half of the probands were 50 to 65 years old at the time of operation. The average age was 52 years, and was the same in both sexes. The average age of those with primary coxarthrosis was 8 years higher than of those with secondary coxarthrosis, or 56 and 48 years, respectively. The youngest proband at operation was 17 years and the oldest 74 years.

d Age at Follow-up

Over half of the probands were 60 to 75 years old The average age was 61 years (Fig 3) and was the same in both sexes The

average age of the probands with primary coxarthrosis, mainly bilateral, was 66 years, while the corresponding age of the probands with secondary coxarthrosis, mainly unilateral, was 57 years. The youngest proband at follow-up was 19 years and the oldest 84 years

Males	1		2	4	3	4	16	8	3	6	1	- 48

Fig 3 Age Distribution at Follow up

e Follow-up Period

The interval between operation and the follow-up examination was 2 to 22 years For 102 of the probands it was at least 5 years The average interval was 10 years, and was the same for females and males and for unilateral and bilateral coxarthrosis

f Length of Hospitalization

Four probands were referred to their local hospitals a few days postoperatively for further convalescence The rest were discharged as soon as they could walk and manage at home, usually with domestic help

Of the remaining probands, 109 operated upon once, spent on the average 3 3 months (range 1-7 months) in hospital, 9 operated upon twice, 5 7 months (range 2 5-11 months), and the remaining 3 operated upon three or four times, 8 months (range 4 5-10 months)

The above figures include only operations for securing fusion, i e no osteotomies, extraction of nails or sequestrectomies etc

C. Methods

1. Follow-up Procedure

The follow-up procedure was carried out from February 1968 to February 1969 and comprised a registration of the mode of static support, radiographic and clinical examinations

The whole procedure took 2 5-3 hours. As a rule the static support test was carried out first and was performed by an assistant at the Balance Laboratory of the Department of Otolaryngology in Lund Thereafter the radiographic examination was performed at the Department of Radiology, Section II, which serves the Orthopaedic Department. The radiographic examination was followed immediately by the clinical examination, which was always made by the author.

2 Static Support Test

a Purpose

The purpose of the test was to find out:

i) which leg was preferred under static conditions in unilateral and bilateral coxarthrosis;

ii) whether this support pattern was influenced by the position of the fused hip and/or discrepancy in relative leg length;

iii) the number of shifts of leg most loaded and to compare this with what may be considered normal in healthy individuals;

iiii) whether the probands were able to load both legs equally and whether the ipsilateral and contralateral leg could be used for supporting leg (> 60% of body weight) alternately for a short period of time,

iiiii) the support pattern during Romberg's test and compare this with the preferred pattern in the first part of the test

Of further interest was a comparison of the opinion of the probands and the results of the test as regards which leg was generally loaded with more than half of body weight.

b Equipment

At the Balance Laboratory of the Otolaryngological Department, certain equipment was used for registration of Romberg's test (Henriksson, Johansson, Olsson and Östlund 1967).

After slight modifications this equipment proved well suited for studying the pattern of static weight distribution It consisted of a platform (109 x 90 cm, height 21 5 cm) in two sections, enclosing two electric scales (Bofors Co , Sweden), *working on strain gauge* principles (Fig 4) The scales, one for each foot contained two strain gauges each The platform and scales were movable easily adjustable to individual requirements and indistinguishable from quite firm footing

A voltage proportional to the weight on each scale was registered on an inkwriter (Mingograf) calibrated so that 100% of body weight gave identical amplitude i e equal deviation from the base line which represented even loading on both scales

By recording the difference in voltage between the scales on one of the channels of the inkwriter (Channel 1) the difference in load on the scales was measured On Channel 2 the algebraic values for deviations (deviations toward the right minus deviations toward the left or vice versa) were electrically integrated and recorded (Fig 4)

c Procedure

The static support test was developed by the author The test lasted for exactly 20 minutes With calibration and various delays the actual measuring time was often 5 to 10 minutes longer

After adjusting the distance between the scales to the comfort of the proband the scales were calibrated The probands were not informed in advance of the various parts of the test To begin with they were asked to stand in their habitual manner as when waiting for a bus or standing in a queue *All other instructions were given at* appropriate intervals

i) Preferred mode of support was registered for two 5 minute *periods interrupted by 5 minutes* of equal support on both legs (vide infra) This interruption had a dual purpose first to find whether the probands returned to the same mode of support and then to find whether the frequency of shifts increased in the latter period

ii) During a 5 minute period the probands were asked to load both legs as equally as possible They were routinely reminded of this about once every minute

iii) In direct continuation of the above 15 minutes the probands were instructed first to load the mobile leg for 2 minutes in a relaxed manner to relieve *the fused* leg and then vice versa by loading the fused leg

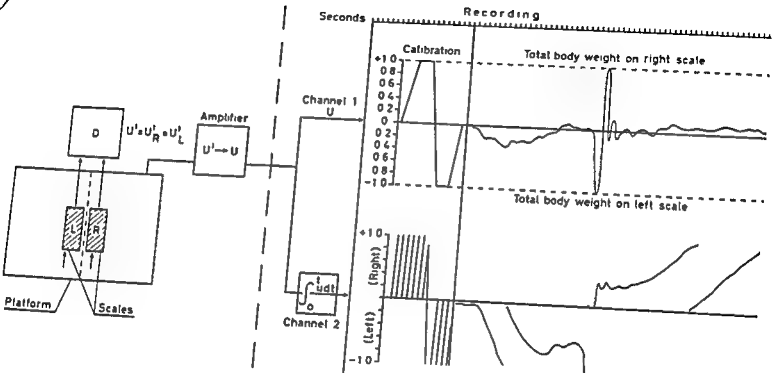

Fig 4 Recording of Static Support Pattern

After slight modifications this equipment proved well suited for studying the pattern of static weight distribution It consisted of a platform (109 x 90 cm, height 21 ■ cm) in two sections, enclosing two electric scales (Bofors Co , Sweden), working on strain gauge principles (Fig. 4). The scales, one for each foot contained two strain gauges each The platform and scales were movable, easily adjustable to individual requirements and indistinguishable from quite firm footing

A voltage proportional to the weight on each scale was registered on an inkwriter (Mingograf), calibrated so that 100% of body weight gave identical amplitude, i e equal deviation from the base line, which represented even loading on both scales

By recording the difference in voltage between the scales on one of the channels of the inkwriter (Channel 1), the difference in load on the scales was measured On Channel 2 the algebraic values for deviations (deviations toward the right minus deviations toward the left or vice versa) were electrically integrated and recorded (Fig 4)

c Procedure

The static support test was developed by the author The test lasted for exactly 20 minutes With calibration and various delays the actual measuring time was often 5 to 10 minutes longer

After adjusting the distance between the scales to the comfort of the proband, the scales were calibrated The probands were not informed in advance of the various parts of the test To begin with, they were asked to stand in their habitual manner as when waiting for a bus or standing in a queue All other instructions were given at appropriate intervals

ii) During a 5 minute period the probands were asked to load both legs as equally as possible They were routinely reminded of this about once every minute

iii) In direct continuation of the above 15 minutes, the probands were instructed, first to load the mobile leg for 2 minutes in a relaxed manner to relieve the fused leg, and then vice versa by loading the fused leg

a line representing the pelvic horizontal (vide infra) and a line drawn along the inner contour of the proximal femoral shaft,

Table IV. Assessment of Radiographic Severity

(Fr Heripret, Danielsson and Dymling, 1964)

Severity		Index
Osteophytes-		
	None	0
	Visible on one pole of the joint	1
	Visible on both poles	2
	Bulky on both poles	3
Joint Space		
	Normal	0
	Narrowed but larger than half normal width	1
	Smaller than half normal width	2
	Effaced over more than half femoral contour	3
Structure		
	Normal	0
	Hyperdensity or cysts in caput or acetabulum	1
	Hyperdensity or cysts in caput and in acetabulum	2
	Grossly destroyed	3
Associated anomalies		
	None	0
	Double Floor	1

Radiograms of the lumbar spine and knees had not always been taken before the operation Comparison with the radiograms obtained at follow-up was therefore rarely possible, but these radiograms demonstrated arthrotic changes in other adjoining joints

a Procedure

The hip joint was always fused in a varying degree of flexion. If ab- and adduction is determined radiographically with the central ray directed on the symphysis, the flexed position will tend to increase the angle of abduction measured on the film and decrease that of adduction

iii) Finally, Romberg's test was carried out, the probands being instructed to stand with their eyes closed for as long as possible up to 1 minute.

All stages of the test were done successively. This proved fairly strenuous for some of the probands. None of the probands expressed difficulty in assuming or maintaining their habitual standing position Two probands were allowed to use a cane to keep their balance. Eleven probands were tested twice at 3 to 11 month intervals. No appreciable difference was found between the results of the two tests.

d. Calculation

The tracings on Channel 1 (Fig. 4) represented the difference in loading of the two scales expressed as body weight (P). The tracings on Channel 2 represented the integrated loading difference expressed as body weight multiplied by time. The speed of integration was adjusted so that, during calibration with total body weight on one scale, the integrator was filled in one second, each stroke representing "1 body weight' per second (Fig. 4).

After each period of the test, the difference between the number of strokes on both sides of the base line was divided by the number of seconds in that period. The result gave a constant (k), by which the average loading on each of the two scales could be calculated from the expression $P = \frac{1 + k}{2}$ for the leg supporting the major part of bodyweight and $P = \frac{1 - k}{2}$ for the other during the period

To avoid repitition and misunderstanding it was found convenient to express average loading of the fused leg as a percentage of bodyweight. Thus, if e g. the average weight supported by the mobile leg during a certain period was 65% of bodyweight, it was expressed as 35% f l. (fused leg).

3 Radiographic Examination

At follow-up all probands were subjected to radiographic examination af the pelvis, hips, lumbar spine and knees The aims of the radiographic examination were primarily,

a) to assess radiographic signs of coxarthrosis as compared with those in preoperative radiograms The severity of the changes was classified according to a numerical index (Table IV),

b) to determine the degree of ab- and adduction of the fused hip, by

The neutral angle, according to Weinreich (1960), is that in which the midpoint of the hip, knee and ankle joint are joined by a vertical line, representing symmetrical weight distribution between both legs. In this mechanical midposition, which is equivalent to a distance of about 18 cm between the midpoints of the two ankle joints, the long axis of the femur is adducted toward the midline

Lindahl (1965) chose a basic position with the feet together In this position the neutral angle is formed by the pelvic horizontal and the leg (femur) The angle varies with the width of the pelvis and the leg length This factor must be taken into account to secure uniform measurements The neutral angle was calculated from the distance between the femoral heads on the radiograms and the length of the normal leg, measured clinically

ii) Calculation of the Neutral Angle The neutral angle was calculated from the expression $\cos \alpha = \frac{P}{2L}$, P denoting the distance between the femoral heads and L the length of the normal (mobile) leg

When the angle of the fused hip, as measured on the radiograms, was smaller than the neutral angle, the difference denoted the degree of adduction in the fused hip and, conversely, when greater, the degree of abduction This method was employed throughout the investigation It was tested by calculating the neutral angle in 10 normal persons and was found to deviate by at most three degrees from the angle measured directly on their radiograms

4 Clinical Examination

The aim of the clinical examination was to assess and record

a) the range of motion and degree of pain in the mobile hip,

b) the degree of flexion in the fused hip and

c) the state of the lumbar spine and knees

Further notes were made of the probands accounts of their working capacity

The physical examination was carried out in a conventional manner (Method of Measuring and Recording American Academy of Orthopaedic Surgeons, 1965)

Published methods for assessment of pain (Judet & Judet 1952, Shepard 1954, Stinchfield 1957, Danielsson 1964) use a numerical index from (0) 1 to (5) 6 In the author s opinion hip pain was best assessed by its restrictive effects on daily activities and work or sleep and by the use of analgesics rather than by noting starting

In most cases the angle formed by the fused leg and the table could be easily eliminated by extension (lordosis) of the lumbar spine However, owing to stiffness of the back, this was not always complete This source of error was eliminated by the following procedure (focal distance 150 cm).

First Radiogram. With the proband supine on AP projection was taken with vertical direction of the rays, centered immediately above the symphysis Film, size 30 x 40 cm, covering the whole pelvis and upper part of both femoral shafts A metal measuring scale was placed under the proband, i e. between him and a mattress covering the table

Second Radiogram The floating table top was moved laterally about 10 cm to center the beam over the fused hip. Film, size 30 x 40 cm, was placed longitudinally, covering the hip and at least 10 cm of the femoral shaft. The metal scale was in the same position as in the first radiogram.

Conventional frontal and lateral projections of the mobile hip, knees and lumbar spine were obtained.

b. Measurement of the Frontal Position of the Fused Hip

The measurement was made as follows

On the first radiogram a reference line was drawn through the lower ranges of the sacro-iliac joints. On the second radiogram a line was drawn along the inner contour of the upper femoral shaft This radiogram was then superimposed on the first, using the metal scale as a landmark. The reference line of the first radiogram was then traced on the second. The angle thus formed by the two lines, gave the frontal angle of the fused hip.

1) The Neutral Position In clinical practice the frontal position and motion in ab- and adduction have traditionally been measured from a zero position, in which the anterior contour of the thigh forms a right angle with the superior-anterior iliac spines

This position actually represents a considerable degree of abduction in the hip owing to the inclination of the femur toward the median plane In the upright position it will correspond to an abduction of the hip of nearly 10 degrees from the standing position (Charnley 1953)

The neutral angle, according to Weinreich (1960), is that in which the midpoint of the hip, knee and ankle joint are joined by a vertical line, representing symmetrical weight distribution between both legs In this mechanical midposition which is equivalent to a distance of about 18 cm between the midpoints of the two ankle joints, the long axis of the femur is adducted toward the midline

Lindahl (1965) chose a basic position with the feet together In this position the neutral angle is formed by the pelvic horizontal and the leg (femur) The angle varies with the width of the pelvis and the leg length This factor must be taken into account to secure uniform measurements The neutral angle was calculated from the distance between the femoral heads on the radiograms and the length of the normal leg, measured clinically

ii) Calculation of the Neutral Angle The neutral angle was calculated from the expression $\cos \alpha = \frac{P}{2L}$, P denoting the distance between the femoral heads and L the length of the normal (mobile) leg When the angle of the fused hip, as measured on the radiograms, was smaller than the neutral angle, the difference denoted the degree of adduction in the fused hip and, conversely, when greater, the degree of abduction This method was employed throughout the investigation It was tested by calculating the neutral angle in 10 normal persons and was found to deviate by at most three degrees from the angle measured directly on their radiograms

4 Clinical Examination

The aim of the clinical examination was to assess and record

a) the range of motion and degree of pain in the mobile hip,

b) the degree of flexion in the fused hip and

c) the state of the lumbar spine and knees

Further notes were made of the probands accounts of their working capacity.

The physical examination was carried out in a conventional manner (Method of Measuring and Recording American Academy of Orthopaedic Surgeons, 1965)

Published methods for assessment of pain (Judet & Judet 1952, Shepard 1954, Stinchfield 1957, Danielsson 1964) use a numerical index from (0) 1 to (5) 6 In the author s opinion hip pain was best assessed by its restrictive effects on daily activities and work or sleep and by the use of analgesics rather than by noting starting

pain, pain when walking etc Assessment was therefore restricted to the following four grades:

Grade 0: no pain.

Grade 1: slight or occasional pain, rarely interfering with work or daily activities, often relieved by rest and seldom requiring analgesics ,

Grade 3: moderate pain that may periodically interfere with work or activities and requiring frequent use of analgesics.

Grade 5: severe or disabling pain, curbing activities and work, disturbing sleep or so severe that the proband had been granted a disability pension

Functional capacity after the operation was assessed by grading some daily activities and working capacity The grading was based on Shepard's (1954) method, but slightly shortened Thus e g limp and difficulty in putting on socks and shoes were omitted, as these were natural consequences of a successful arthrodesis and were present in all cases (Table XX).

5. Statistical Methods[1)]

Only well known statistical techniques were used (Blom, G 1969), mainly the chi-square test. In a few cases the sign test and Student s t-test were applied.

Statistical significance was described as follows·

$P>0.05$	= not significant
$0.05 > P>0.01$	= almost significant*
$0.01 > P>0.001$	= significant**
$0.001 > P$	= highly significant***

1) Data treated statistically by civil engineer Tore Persson, Department of Mathematical Statistics, University of Lund.

A Static Support Test

1 Preferred Mode of Support in Standing

a Support Pattern

Henriksson et al. (1967) who used *the same equipment as that used in this investigation* (cf. p 13), found that normal persons seemed to deviate on the average 6 – 7% of body weight in the lateral direction. Therefore, deviations from the base line of up to 10% of body weight, were in the present investigation taken to signify equal weight distribution on both legs and henceforth termed equal support (*40%-60% f.l.*). *Accordingly, an average load of* > 60% of body weight on either leg during this part (10 min) of the test, was taken as a sign of a clear preference for the leg in question (supporting leg).

The support pattern obtained with the above differentiation is illustrated in Fig. 5. There were two groups representing an average loading *of* > 60% of body weight on one leg and a middle group with equal loading on both. The mobile leg was used as a supporting leg three times as often as the fused leg.* * *

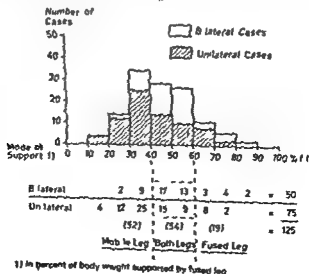

Fig 3 Static Support Pattern Preferred Mode of Support during 10 Minutes

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig. 5. The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear prefere for the mobile leg.

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods. In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support.

Comments

The opinion of the probands as to which leg was generally loaded with more than half of body weight (main support) was compare to the results of the preferred support pattern. The base line (50% of body weight on each leg) divided the material in two parts (Fig. 5), two thirds (84) loading the mobile leg with more than half of body weigh and one third (41) the fused leg*. Six probands had even loading on both legs. These were divided equally among the two groups. The result of the test bore a close resemblance to the opinion of the probands as 87 (70%) thought they generally loaded the mobile leg with more than half of body weight during standing, 29 (23%) the fused leg an 9 (7%) both legs equally.

The opinion of the probands regarding the leg mostly used for support during standing was in agreement with the results of the test in over 75% of the cases Most of the 32 probands whose opinion differed from the results of the test, displayed no clear preference for either leg (40% - 60% f.l.).

Hohman (1962) studied the support pattern in 75 cases with hip arthrodesis by letting them stand on two scales for 15 minutes He found that the fused leg was loaded in the following manner up to 1/4 of body weight 19%, 1/4 - 1/2 of b w 51% and over half of body weight 30%. The corresponding figures in the present material were up to 1/4 of b.w. 7%, 1/4 - 1/2 of b w 60% and over half of body weight 33%, and thus in good agreement with those given by Hohman Further, both investigations revealed that support by the fused leg and fairly equal support by both legs was more common than what is given in other reports based on clinical observations but without measuring devices (Table V)

Table V Preferred Mode of Support in Standing.
Earlier Studies compared with the Present.

b Support Pattern in Relation to Frontal Position of Fused Hip.

There was a difference in support pattern between probands with adduction and those with abduction of the fused hip. In the former the fused leg was more often used for main support than in the latter. Of 38 probands with adduction of the fused hip, 16 used the fused leg for main support, compared with 25 of the 87 probands with abduction.

Cases with from 5 degrees of adduction to 5 degrees of abduction in the fused hip were pooled and the group was called *neutral* (Table VI). There were 58 cases with neutral position, 12 with adduction (range 6 -12) and 55 cases with abduction of the fused hip (range 6'-25'). The distribution of the 41 cases which used the fused leg for main support, within the adduction, neutral and abduction groups was such that they constituted about 1/2, 1/3 and 1/4 of the cases in each group. The relative proportions within the three groups of the 19 cases which used the fused leg as supporting leg (> 60% f.l.) was roughly 1/4, 1/5 and 1/18 respectively.

Loading of the fused leg thus seemed to be facilitated by the neutral or adducted position.

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig. 5. The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear preference for the mobile leg.

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods. In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support.

Comments

The opinion of the probands as to which leg was generally loaded with more than half of body weight (main support) was compared to the results of the preferred support pattern. The base line (50% of body weight on each leg) divided the material in two parts (Fig. 5), two thirds (84) loading the mobile leg with more than half of body weight and one third (41) the fused leg.* Six probands had even loading on both legs. These were divided equally among the two groups. The result of the test bore a close resemblance to the opinion of the probands as 87 (70%) thought they generally loaded the mobile leg with more than half of body weight during standing, 29 (23%) the fused leg an 9 (7%) both legs equally.

The opinion of the probands regarding the leg mostly used for support during standing was in agreement with the results of the test in over 75% of the cases Most of the 32 probands whose opinion differed from the results of the test, displayed no clear preference for either leg (40% - 60% f.l.).

Hohman (1962) studied the support pattern in 75 cases with hip arthrodesis by letting them stand on two scales for 15 minutes. He found that the fused leg was loaded in the following manner up to 1/4 of body weight 19%, 1/4 - 1/2 of b w 51% and over half of body weight 30%. The corresponding figures in the present material were up to 1/4 of b w. 7%, 1/4 - 1/2 of b w. 60% and over half of body weight 33%, and thus in good agreement with those given by Hohman Further, both investigations revealed that support by the fused leg and fairly equal support by both legs was more common than what is given in other reports based on clinical observations but without measuring devices (Table V)

Table V Preferred Mode of Support in Standing.

b Support Pattern in Relation to Frontal Position of Fused Hip.

There was a difference in support pattern between probands with adduction and those with abduction of the fused hip In the former the fused leg was more often used for main support than in the latter. Of 38 probands with adduction of the fused hip, 16 used the fused leg for main support, compared with 25 of the 87 probands with abduction.

Cases with from 5 degrees of adduction to 5 degrees of abduction in the fused hip were pooled and the group was called neutral (Table VI) There were 58 cases with neutral position, 12 with adduction (range 6 -12) and 55 cases with abduction of the fused hip (range 6°-25°). The distribution of the 41 cases which used the fused leg for main support, within the adduction, neutral and abduction groups was such that they constituted about 1/2, 1/3 and 1/4 of the cases in each group The relative proportions within the three groups of the 19 cases which used the fused leg as supporting leg (> 60% L.I) was roughly 1/4, 1/5 and 1/18 respectively

Loading of the fused leg thus seemed to be facilitated by the neutral or adducted position.

The difference in support pattern between the unilateral and bilateral cases is also illustrated in Fig. 5. The main difference was that in two thirds of the bilateral cases both legs were loaded equally, whereas in over half of the unilateral cases there was a clear preferenc for the mobile leg.

One hundred and twelve of the probands showed the same support pattern in both 5 minute periods. In the 13 probands who did not, the mean value of both periods placed all but one within the group with equal support.

Comments

The opinion of the probands as to which leg was generally loaded with more than half of body weight (main support) was compared to the results of the preferred support pattern. The base line (50% of body weight on each leg) divided the material in two parts (Fig. 5), two thirds (84) loading the mobile leg with more than half of body weight and one third (41) the fused leg. Six probands had even loading on both legs. These were divided equally among the two groups. The result of the test bore a close resemblance to the opinion of the probands as 87 (70%) thought they generally loaded the mobile leg with more than half of body weight during standing, 29 (23%) the fused leg an 9 (7%) both legs equally.

The opinion of the probands regarding the leg mostly used for support during standing was in agreement with the results of the test in over 75% of the cases. Most of the 32 probands whose opinion differed from the results of the test, displayed no clear preference for either leg (40% - 60% f.l.).

Hohman (1962) studied the support pattern in 75 cases with hip arthrodesis by letting them stand on two scales for 15 minutes. He found that the fused leg was loaded in the following manner up to 1/4 of body weight 19%, 1/4 - 1/2 of b.w. 51% and over half of body weight 30%. The corresponding figures in the present material were up to 1/4 of b.w. 7%, 1/4 - 1/2 of b.w. 60% and over half of body weight 33%, and thus in good agreement with those given by Hohman. Further, both investigations revealed that support by the fused leg and fairly equal support by both legs was more common than what is given in other reports based on clinical observations but without measuring devices (Table V).

Comments

According to Seevald and Debrunner (1964) one of the reasons why *most of their cases (Table V)* loaded the mobile leg was excessive flexion in the fused hip. In the present material however, large flexion angles did not seem to have any adverse effect on loading of the fused leg.

d. Frequency of *Shifting Leg of Main Support*

The normal, energy saving static posture requires that body weight can be shifted freely (cf. p. 31) from one leg to the other. The number of shifts during the static support test was shown by the tracings of the inkwriter (Fig. 4). *In the following a shift means that more than half of body weight was shifted from one leg to the other for at least 15 seconds.*

The *frequency of shifting was found to vary considerably with the* support pattern Those showing preference for one leg shifted more *often in the early 5 minute period whereas those with* equal support displayed increase in the number of shifts in the latter half of the test period. Further, the average total frequency of shifts was highest for those with equal support*** (Table VIII).

Table VIII. Preferred Mode of Support in Standing versus Number of Shifts of Supporting Leg

Support Pattern	Number of Shifts First 5 min. Period	Second 5 min. Period	Total	Average Number of Shifts
<40% f.l.	22	15	37:52	0.71
40%-60% f.l.	69	86	155:54	2.9
>60% f.l.	18	6	24:19	1.3
Total	109	107	216:125	1.7
Average Number of Shifts	0.9	0.9		

Comments

Smith (1953) observed 250 persons standing in bus queues and found that most of body weight was shifted among the legs, on the average, every 30 seconds. He found asymmetrical standing, i.e. what he considered nearly the whole weight of the body supported by one leg, to

Table VI Preferred Mode of Support in Standing versus Frontal Position of Fused Hip

Mean Support f l	65%	67%	63%	67%	61%	56%		63% f.l.

c Support Pattern in Relation to Sagittal Position of Fused Hip.

The sagittal position of the fused hip varied from 15 to 55 degrees of flexion. The material was divided into three groups with regard to the angle of flexion. There were 39 probands with fairly small angles (range 15°-29°), 60 with moderate (range 30°-39°) and 26 with large angles of flexion (range 40°-55°).

The 19 probands who showed a clear preference for the fused leg were distributed among the three groups, roughly making, 1/6, 1/9 and 1/4 of the cases in each. The corresponding proportions for the 41 probands with main support by the fused leg was, 2/6, 2/7 and 2/5 (Table VII).

Table VII. Preferred Mode of Support in Standing versus Degree of Flexion of Fused Hip

Support Pattern	Degree of Flexion 10°-19°	20°-29°	30°-39°	40°-49°	≥50°	Total
<40% f.l.		14	28	9	1	52
40%-60% f.l.	2	17	25	9	1	54
>60% f.l.		6	7	5	1	19
Total	2	37	60	23	3	125
Number of Prob. with Main Supp. by Fused Leg	14		16	11		41
Mean Support f.l	62% f.l.		62% f.l.	65% f.l.		63% f.l.

Comments

According to Seevald and Debrunner (1964) one of the reasons why most of their cases (Table V) loaded the mobile leg was excessive flexion in the fused hip. In the present material however, large flexion angles did not seem to have any adverse effect on loading of the fused leg.

d Frequency of Shifting Leg of Main Support

The normal, energy saving static posture requires that body weight can be shifted freely (cf. p. 31) from one leg to the other. The number of shifts during the static support test was shown by the tracings of the inkwriter (Fig. 4). In the following a shift means that more than half of body weight was shifted from one leg to the other for at least 15 seconds.

The frequency of shifting was found to vary considerably with the support pattern Those showing preference for one leg shifted more often in the early 5 minute period whereas those with equal support displayed increase in the number of shifts in the latter half of the test period Further, the average total frequency of shifts was highest for those with equal support*** (Table VIII).

Table VIII. Preferred Mode of Support in Standing versus Number of Shifts of Supporting Leg

Support Pattern	Number of Shifts: First 5 min Period	Number of Shifts: Second 5 min Period	Total	Average Number of Shifts
<40% f.l.	22	15	37-52	0.71
40%-60% f.l.	69	86	155 54	2.9
>60% f.l	18	6	24-19	1.3
Total	109	107	216-125	1.7
Average Number of Shifts	0.9	0.9		

Comments

Smith (1953) observed 250 persons standing in bus queues and found that most of body weight was shifted among the legs, on the average, every 30 seconds. He found asymmetrical standing, i.e. what he considered nearly the whole weight of the body supported by one leg, to

be about four times as frequent as symmetrical standing

Hohman (1962) studied the preferred manner of support of 75 probands with arthrodesis of the hip in standing during 15 minutes He found that during the first few minutes the body weight was frequently shifted from one leg to the other, as a rule followed by a certain stability with slow variation A change of supporting leg was rarely noted thereafter

The remarkably small number of shifts during the static support test, compared with observations in normal persons, may be an indication of the restrictive effect of the fusion in this respect The lower frequency of shifts among those mainly loading one leg suggests that the support pattern was deeply rooted and uniform as shifts were less frequent in the second half of the test Thus the two to threefold frequency of shifts among the probands who displayed equal support may be explained by the fact that they had more symptoms in the mobile hip and therefore were less comfortable in any position (Table IX)

e Support Pattern in Relation to Leg Length Discrepancy

One hundred and seven of the probands had a discrepancy in relative leg length, 101 shortening and 6 lengthening of the fused leg In 18 cases no difference was found

The distribution according to support pattern and frontal position of the fused hip of the 52 cases with 2 cm or more of uncompensated shortening of the fused leg, during the static support test, was largely the same as that of the material as a whole (Table VI) Thus, 22 showed equal support and the rest preferred support by one leg (19 the mobile and 11 the fused leg) Still, the adducted or neutral position and support by the fused leg were somewhat more common in the 52 cases than in the rest of the material

Equal support was on the other hand less common among the 21 cases with 3 cm or more shortening Fifteen of these had preferred support by one leg (9 the mobile and 6 the fused leg)

Of the 6 cases with relative lengthening of the fused leg from 1 to 4 cm (average, 2 cm), 2 had compensatory heel raises on the mobile side Four had equal loading on both legs and 2 preferred the mobile leg

Eighteen cases had no measureable discrepancy in leg length Eight loaded both legs equally, 7 preferred the mobile and 3 the fused leg

Table IX. Preferred Mode of Support in Standing versus Increase in Radiographic Index and Pain in Mobile Hip.

Support Pattern	Increase in Radiogr Index											Total	Average Increase In Radiogr. Index	Number	Pain Index	Number
	0	1	2	3	4	5	6	7	8	9	10					
<40% f.l.	33	8	6	1	1	1	2					52	0.8	19	1.0	24
40%-60% f.l.	14	18	9	4	3	4	1		1			54	1.7	40	1.4	31
>60% f.l.	10	1	2	3			2	1				19	1.7	9	1.7	13
Total	57	68										125	1.4	68	1.3	68

be about four times as frequent as symmetrical standing

Hohman (1962) studied the preferred manner of support of 75 probands with arthrodesis of the hip in standing during 15 minutes He found that during the first few minutes the body weight was frequently shifted from one leg to the other, as a rule followed by a certain stability with slow variation A change of supporting leg was rarely noted thereafter

The remarkably small number of shifts during the static support test, compared with observations in normal persons, may be an indication of the restrictive effect of the fusion in this respect The lower frequency of shifts among those mainly loading one leg suggests that the support pattern was deeply rooted and uniform, as shifts were less frequent in the second half of the test Thus the two to threefold frequency of shifts among the probands who displayed equal support, may be explained by the fact that they had more symptoms in the mobile hip and therefore were less comfortable in any position (Table IX)

e Support Pattern in Relation to Leg Length Discrepancy

One hundred and seven of the probands had a discrepancy in relative leg length, 101 shortening and 6 lengthening of the fused leg In 18 cases no difference was found

The distribution according to support pattern and frontal position of the fused hip of the 52 cases with 2 cm or more of uncompensated shortening of the fused leg, during the static support test, was largely the same as that of the material as a whole (Table VI) Thus, 22 showed equal support and the rest preferred support by one leg (19 the mobile and 11 the fused leg) Still, the adducted or neutral position and support by the fused leg were somewhat more common in the 52 cases than in the rest of the material

Equal support was on the other hand less common among the 21 cases with 3 cm or more shortening Fifteen of these had preferred support by one leg (9 the mobile and 6 the fused leg)

Of the 6 cases with relative lengthening of the fused leg from 1 to 4 cm (average, 2 cm), 2 had compensatory heel raises on the mobile side Four had equal loading on both legs and 2 preferred the mobile leg

Eighteen cases had no measureable discrepancy in leg length Eight loaded both legs equally, 7 preferred the mobile, and 3 the fused leg

2 Instructed Modes of Support in Standing

a Equal Support by Both Legs

Eighty nine (71%) of the probands managed equal support for a period of 5 minutes. Of the 36 probands who failed, 24 retained their preference for loading the same leg as they had in the first part of the test, 18 of them the mobile leg and 6, the fused leg Of the remaining 12 probands, 8 who in the first part of the static support test showed equal support, had changed to support by one leg, 7 by the mobile leg and 1 by the fused leg Of the remaining 4 cases, 3 had changed from support by the mobile leg to the fused and 1 vice versa

Comments

It is difficult to explain why these 36 cases could not manage equal support, for e.g leg length discrepancy, extreme positions of the fused hip or changes in the mobile hip or other joints, were not more common in this group than in the rest of the material.

b Support by Fused Leg

One hundred and eleven (89%) of the probands could use the fused leg for support (>60% of b w) during a period of 2 minutes This invariably involved more or less leaning toward the fused side and forwards

Fourteen probands could not load the fused leg to such an extent, average 54% f 1 (range 41%-60% f 1) Ten had preferred the mobile leg in the former part of the static support test Their support pattern thus appeared to be confined to one mode Possible contributary causes in 8 of the latter were as follows 5 had a combined abduction of the fused hip and severe arthrosis of the mobile hip with little or no frontal motion, and 3 had pain in the ipsilateral knee when standing for any length of time

c Support by the Mobile Leg

One hundred and sixteen (93%) of the probands could use the mobile leg for support for two minutes. Of the 9 probands who could not, 5 had equal support in the first part of the static support test and 3 had preferred the fused leg The remaining one of these 9 was the oldest proband in the material, an 84 year old woman with pain in the mobile

Comments

Relative shortening of the fused leg was slightly more common in the 41 cases with main support by the fused leg than in the rest of the material. Twenty of the 41 cases had an uncompensated shortening of 2 cm or more compared with 32 of the remaining 84.

Large, uncompensated shortenings (≥ 3 cm) were most common among the 19 cases with preference for the fused leg. Thus, one third (6) of these compared with one sixth (9) of those preferring the mobile leg and only ninth (6) of those with equal support, had such large shortening.

Many of the probands had been reluctant to use a heel raise to compensate shortening of the fused leg. Only 46 of the 101 cases used a heel raise more or less regularly. Such compensation was seldom used if the shortening was less than 3 cm, but even 13 of the 41 probands with a shortening of 3 cm or more never used one Of the 46 probands using a heel raise, 9 used it only intermittently or during working hours.

Practically all of the probands with a shortening of 2 cm or more had been prescribed a heel raise after operation. However, half of them had stopped using it because they felt that the fused leg had become too long and was more "in the way", often causing them to stumble or fall.

f Support Pattern versus Radiographic Deterioration and Pain

The incidence and amount of radiographic deterioration and pain in the mobile hip was largest among those of the probands who preferred equal support or support by the fused leg (Table IX) Roughly two thirds of the latter showed increase in radiographic severity compared with one third of those who preferred the mobile leg The difference was significant As regards pain, three fifths of the former and nearly half of the latter had pain in the mobile hip

The degree of deterioration and pain was thus least among the 52 probands who preferred the mobile leg for support This was in good agreement with the views of many of the probands who stated that, as symptoms increased in the mobile hip, more of their body weights had been transferred to the fused side

3 Discussion

The mode of standing and the forces acting on the hip joint under normal and pathologic conditions have been investigated by a number of authors (Walmsley 1933, Akerblom 1948, Kelton and Wright 1949, Smith 1953, Schede 1956, Fürmaier 1959, Weinreich 1960, Denham 1959 Hohman 1962, Jonsson and Steen 1962, Casuccio 1964, Rydell 1966, Henriksson et al 1967) The consensus of opinion is that if the standing position is to be maintained for any length of time body weight is not supported equally by both legs. Instead the posture of at ease is adopted, i e the bulk of body weight resting on one leg with Trendelburg s sign positive In this posture the large joints of the weight bearing extremity, hip and knee, are stabilized in the extended position by the strong ligaments reinforcing their joint capsules Muscle activity is then largely confined to the interplay of antagonists for keeping balance, further facilitated by the passive counterweight of the unloaded leg (Fig 6 b) This is the energy saving standing posture adopted during longer periods in which body weight is alternately shifted from one leg to the other, whereas maintaining balance on both legs requires considerably more muscle activity A requirement for adopting and maintaining the former posture is that the line of body weight must pass through the center of the supporting foot, dividing the body into two balanced halves A necessary condition for this is that the line of body weight passes medially to the supporting hip joint, which in turn involves lateral translation of the pelvis toward the supporting side along with lowering of the pelvis toward the unloaded side The only other way of supporting body weight mainly by one leg is that with Trendelenburg s sign negative which involves elevation of the pelvis on the unloaded side, abduction of the supporting hip joint and lateral translation of the pelvis along with a lumbar scoliosis convex toward the same side (Fig 6 c) The posture with Trendelenburg s sign negative implies a continuous muscular effort, and is therefore not adopted for longer periods, *in daily life only* when walking

After arthrodesis of the hip, standing on the fused leg can no longer be facilitated by translation of the pelvis toward the loaded side by adducting the supporting hip There are two possible ways by which the arthrodesed person can load the operated side with more than half of his body weight In order to establish balance he can either lean the upper part of the body toward the side of support (Fig 6 d) or, by

hip and suffering from vertigo, which might perhaps explain the inconclusive results of the test as, in this part she had 46% f.l. but 35% f.l. in the first part of the test. Of the 9 probands 6 had severe changes in the mobile hip with little or no frontal motion and, with pain (5 cases).

d. Romberg's Test

Finally, Romberg's test was carried out. Most of the probands managed to stand with their eyes closed for about 35-40 seconds or more. Ninety of the probands displayed the same support pattern as they did in the first part of the test.* * *

The support pattern was thus found to have almost the same features as that of the first part of the static support test. The main difference was that equal support by both legs was slightly more common in this part. Thus 22 probands who preferred one leg in the first part had changed to equal support whereas 9 probands with equal support in the first part, had changed to support (<40% f.l.) by the mobile leg, and 1 to the fused leg. Thus the final support pattern in Romberg's test was: <40% f.l. = 45; 40% - 60% f.l. = 66 and >60% f.l. = 14 probands.

Comments

The results of the second part of the static support test showed that in general the probands were able to load whichever leg they chose when a conscious effort was made to do so. However, a few probands did not seem to have much choice in this regard due to stiffness and/or pain in the mobile hip. For many of the probands support by the fused leg for 2 minutes proved exceedingly fatiguing and many expressed relief when this part of the test was over.

As a rule, support by the mobile leg was obviously better tolerated, even by many of those suffering from pain in the mobile hip. An interesting feature of the final period of the static support test was that most of the probands resumed their preferred mode of support from the first part of the test. This was interpreted as a further sign that the support pattern displayed was characteristic of the individual.

equal support pattern. Thus, incidence and degree of pain in the mobile hip was least in the 52 cases who showed preference for the mobile leg.

As regards frontal position, main support by the fused leg appeared to be facilitated by the neutral or adducted position of the fused leg.

In more than half of the 41 cases with main support by the fused leg a combination of the above factors occurred. On one hand there was relative shortening and neutral or adducted position of the fused hip and, on the other hand, pain and/or stiffness of the mobile hip.

Symptoms from the knees did not seem to have a decisive influence on the support pattern although an occasionally contributary role was probable Seventy six probands had knee symptoms, mostly in the form of slight and/or occasional pain. In 52 of these radiographic signs of gonarthrosis were found at follow-up. Radiographic changes were more common and slightly more advanced on the fused side

Of the 19 probands who used the fused leg for support, 15 had some pain in the knees, 10 in the ipsilateral knee (fused side), 1 in the contralateral and 4 in both. Of the 52 probands who used the mobile leg for support, 13 had knee symptoms, 4 in the ipsilateral (fused side) knee, 3 in the contralateral and 6 in both. Of the 54 probands with equal support, 48 had symptoms from the knees, 24 in the ipsilateral, 6 in the contralateral and 18 in both knees.

Pain or fatigue in the lumbar region was a common complaint during protracted standing and sitting Such symptoms were reported by 75 probands, 32 of whom felt that this impaired their standing and walking capacity. Sixty three of the former and 28 of the latter had radiographic signs of lumbar spondylarthrosis.

A slight increase in the incidence of lumbar pain with the degree of flexion in the fused hip was noted. Thus, one half (19) of the 38 probands with small degrees (10°-29°) of flexion, compared to three fourths (18) of the 26 with large flexion (40°- 50°) angles had back pain

4 Conclusions

The support pattern when standing in a free or preferred manner showed that after arthrodesis of the hip the fused extremity was seldom used as the supporting leg it was intended to become. Eighty five percent of the probands either displayed equal support or prefer-

forcibly lifting up the mobile side, the whole (fused) coxofemoral region can be brought to rotate around the axis of the subtalar joints until the line of gravity coincides with the supporting foot (Fig. 6 e). Both these postures require continuous muscular effort for keeping balance along with more or less compensatory scoliosis, the dimensions of which is dependent largely on the degree of abduction of the fused hip.

The results of the static support test were in agreement with the above considerations Two thirds of the probands loaded the mobile leg with more than half of their body weight and 12% of the total number of probands used the mobile leg for support (> 60% of b w by choice, whereas only 15% chose the fused leg for support The question then arises in what respect the probands loading the fused leg differed from the rest Naturally, a number of factors may influence the choice of leg for support, e g relative leg length, position of the fused hip, state of the mobile hip and symptoms from other adjoining joints, chiefly the back and knees

Those probands who mostly loaded the mobile leg were of the opinion that support by the mobile leg was more comfortable, whereas main support by the fused leg was more tiring both generally and for the back. More seldom the fused leg was spared owing to the feeling that it was still the sick one and had to be protected. This impression seemed real for a few probands and may have been a factor the importance of which is hard to estimate. A few probands reported that they avoided loading the fused leg in public as they felt their buttocks protruded too markedly.

The probands who mostly loaded the fused leg gave entirely different reasons. Most of them thought the mobile leg had become too long after the operation. Those with large relative shortening of the fused leg were more or less compelled to stand with most of body weight on one leg or the other and some of these probands preferred standing on the fused leg than on the mobile leg, with the fused one hardly reaching the ground. This was in agreement with the results of the test as a large, relative shortening of the fused leg appeared to induce support by one leg.

Many of the probands in whom the mobile hip had become painful in the interval between the operation and the follow-up examination, reported that they had always used the mobile leg for support until it had become painful Only then had they begun to shift more of body weight over to the fused side This applied to many of the probands with an

ence for loading the mobile leg. The support pattern registered by Hohman (1962), in 75 hip-arthrodesed subjects, showed similar results (cf. p. 22)

Not before the mobile hip had become painful or more painful than preoperatively, had more of body weight been shifted to the fused side by a conscious effort. This was borne out both by the probands' accounts and by the significantly higher incidence and degree of changes and pain in the mobile hip in those probands who displayed equal support and support by the fused leg.

Loading on the fused leg appeared to be facilitated by the neutral or adducted position of the fused hip and by shortening of the fused leg. On the other hand, the degree of flexion of the fused hip was not found to affect the support pattern.

The support pattern was very uniform in different parts of the test and shifts were markedly scarce compared with what may be considered usual in normal subjects.

In view of the results of the test and the opinion of the probands, it was concluded that the alleged supporting role of the fused leg has not been based on factual evidence.

B. Radiographic Examination

1. Arthrotic Deterioration of Mobile Hip

a. With Regard to Radiographic Appearance at Operation

i. Unilateral Coxarthrosis. Of the 75 cases without signs of arthrosis of the mobile hip at operation, 31 had developed such signs by the time of follow-up (Table IV) The average radiographic severity of the 31 hips was 1 9 index points (range 1-6), (Table X) Of these 31 cases, 16 showed only signs of incipient arthrosis. In 8 of the latter, fused because of secondary arthrosis, progress consisted of an osteophyte on one pole. The remaining 8, fused because of primary arthrosis showed either narrowing of the joint space or structural changes. In the remaining 15 cases reduction of the joint space was the most common finding in both types of arthrosis (9 secondary and 6 primary)

In unilateral coxarthrosis the course of the mobile hip was usually favourable for the first few years. Radiographic changes were mostly mild and although the incidence of arthrosis rose sharply after 5 years, two thirds of the hips showed no signs of arthrosis up to 10 years after operation Of the remaining third, reviewed after a longer interval, half the number deteriorated (Table XI)

ii. Bilateral Coxarthrosis. Of the 50 cases with a varying degree of arthrosis of the mobile hip at the time of operation, the average radiographic severity had increased by 3.1 index points (range 1-8) in 37 (Table XI).

radiographic changes. Thirty of the present 75 unilateral cases were reviewed 2 to 7 years after operation, by which time degenerative changes had appeared in 7. Demigneux et al. (1968) found an incidence of 14 of 92 unilateral cases reviewed 5 to 15 years after operation. The etiological composition was not stated In the present material 18 of the 42 unilateral cases, reviewed 5 to 15 years after operation, had developed signs of arthrosis In a series of 75 cases Hauge (1963) found incipient arthrosis in only 6 of the mobile hips examined 5 to 20 years after the operation. All but 4 had been fused for tuberculosis or some unspecific inflammation. Mean age at follow-up was 36 years. The lower incidence in the last two series compared with the present, was probably due primarily to the higher percentage of secondary coxarthrosis and the lower average age in these two series

Demigneux et al (1968) reviewed 41 cases fused 5 to 15 years previously because of bilateral coxarthrosis. At follow-up 24 had been subjected to mobilizing operations of the other hip (5 before the fusion). Of the remaining cases, 14 had showed signs of mild arthrosis of the mobile hip at operation. At the review all were found to have deteriorated and 11 of them considerably. Merle d Aubigne, Ramadier, Postel, Mozas and Vaillant (1964) reviewed 59 cases arthrodesed 2 1/2 - 12 years previously for bilateral coxarthrosis Deterioration of the mobile hip had occurred in 31 cases, 8 of which had been operated upon Of the present 39 bilateral cases with up to 12 years in follow-up time, 19 had deteriorated

b Type of Arthrosis of Fused Hip

Of the 75 unilateral cases, 50 hips had been operated for secondary, and 25 for primary, coxarthrosis. Of the 31 probands who developed signs of arthrosis 17 had had secondary and 14 primary arthrosis in the fused hip

The average radiographic deterioration of the mobile hip was 0.7 in the 50 secondary, and 1 0 index points in the 25 primary, cases. Of the 50 secondary cases deterioration of the mobile hip was greatest in the 21 cases operated for arthrotic changes secondary to some developmental disturbance, mild in the 18 cases fused because of late effects of coxitis and absent in the 11 cases fused because of late complications of fracture of the femoral neck (Table XIII, A, B)

Of the 50 bilateral cases, 36 had primary and 14 secondary arthrosis of the fused hip at operation. In 28 of the former and in 9 of

Forty one of the bilateral cases had had up to 5 in initial radiographic index. Thirty two of these showed progress. Average incidence and amount of radiographic progress was roughly the same in these five index groups, i.e. four fifths of the probands and over 3.0 index points' increase in each. Of the remaining 9 probands with an initial index of 6 or more, 5 had progressed, on the average 1.8 points.

As in unilateral coxarthrosis, joint space reduction was the commonest sign of progress. Structural changes occurred two and a half times as often as in unilateral coxarthrosis. Eleven of these 37 hips showed only one sign of progress. In 4 of these a new osteophyte had formed while in the 7 others the joint space had become narrowed. In the remaining 26 cases, joint space reduction was also the most common sign (Table X).

The radiographic deterioration of the mobile hip appeared sooner and progressed more rapidly in bilateral than in unilateral coxarthrosis (Table XI). Only one third of these cases had remained stationary for up to 10 years after operation and only one fifth for a still longer interval. The radiographic deterioration was also more severe in the bilateral cases (Figs 10-12, p. 74-79).

The difference in <u>incidence</u> of radiographic signs of arthrotic deterioration between the unilateral and bilateral cases was significant **

Average <u>degree</u> of arthrotic deterioration in the 75 unilateral cases was 0.8 and in the 50 bilateral cases 2.3 index points. The difference was significant *** (Table XII)

Table XII Radiographic Deterioration in *Unilateral and Bilateral Coxarthrosis*

Comments

Danielsson (1964) reviewed 91 unoperated cases (121 hips) from 8 to 12 years (average, 11 years) after clinical and radiographic diagnosis of coxarthrosis The aim was to assess the prognosis of coxarthrosis and to provide a standard of comparison for operated cases Radiographic changes were evaluated by comparison of initial and follow-up radiograms according to the scheme used in the present investigation (Table IV) All 121 hips had structural and/or joint space changes at the time of diagnosis The two materials were well comparable as regards number of hips age (cf p 48) and the average duration of the interval Still in the present material, 10 of the bilateral cases had been reviewed after more than 12 years On the other hand, 85% of Danielsson s series had primary coxarthrosis, against 50% of the present material

Danielsson found that radiographic changes usually progressed (average, 1 4 index points) and that primary coxarthrosis progressed radiographically more than secondary (1 7 $\pm$ 0 13 *versus* 0 7 $\pm$ 0 13)

These figures, when compared with radiographic progress in all the primary (61) and secondary (64) cases in the present material, were found to be almost identical (1 9 versus 1 8 index points)

As all the hips in Danielsson s series had structural and/or joint space changes at the outset, comparison with the bilateral cases was of even greater interest Of the 50 bilateral cases of the present material, the primary also progressed radiographically more than the secondary cases

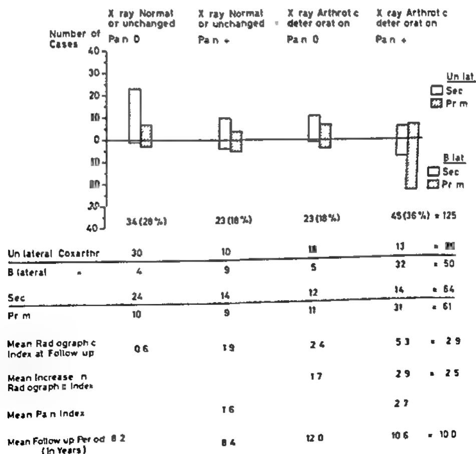
Comments

Danielsson (1964) reviewed 91 unoperated cases (121 hips) from 8 to 12 years (average, 11 years) after clinical and radiographic diagnosis of coxarthrosis. The aim was to assess the prognosis of coxarthrosis and to provide a standard of comparison for operated cases Radiographic changes were evaluated by comparison of initial and follow-up radiograms according to the scheme used in the present investigation (Table IV). All 121 hips had structural and/or joint space changes at the time of diagnosis The two materials were well comparable as regards number of hips, age (cf. p 48) and the average duration of the interval Still, in the present material, 10 of the bilateral cases had been reviewed after more than 12 years On the other hand, 85% of Danielsson's series had primary coxarthrosis, against 50% of the present material.

Danielsson found, that radiographic changes usually progressed (average, 1 4 index points) and that primary coxarthrosis *progressed* radiographically more than secondary (1.7 ± 0 13 versus 0.7 ± 0.13)*

These figures, when compared with radiographic progress in *all* the primary (61) and secondary (64) cases in the present material, were found to be almost identical (1.9 versus 0 8 index points).

As all the hips in Danielsson's series had structural and/or joint space changes at *the outset*, comparison with the bilateral cases was of even greater interest Of the 50 bilateral cases of the present material, the primary also *progressed* radiographically more than the secondary cases.



Of Danielssons's material one third showed no progression and in 8 hips signs of regression were observed. Of the 50 bilateral cases of the present material one fourth showed no signs of progression but in no instance were signs of regression observed

The difference in radiographic deterioration of the mobile hip in the present 36 bilateral, primary cases (2.6 ± 0.12) and Danielsson's 104 hips (1.7 ± 0.13), followed up on the average 11 years after a diagnosis of primary coxarthrosis had been made, was significant***

c. Interval Between Operation and Review

The interval was on the average the same for primary and secondary cases (10 years)

In unilateral coxarthrosis the average interval was over 3 years longer for the cases in which degenerative signs had appeared (Fig 7) Of the 43 cases where the interval was less than 10 years, 14 displayed signs of deterioration compared with 17 of the 32, reviewed after a longer interval (Table XI).

Unilateral Coxarthr	30	10	[illegible]	13	= [illegible]

Mean Pain Index		1 6		2 7	
Mean Follow up Period (In Years)	8 2	8 4	12 0	10 6	= 10 0

Fig 7 Incidence and Degree of Radiographic Deterioration and Pain

Of the 75 unilateral cases 19 were reviewed after 15 to 22 years Eleven of these showed an increase in radiographic severity from 1 to 6 points (average 2 1 index points) whereas 8 had remained stationary

In bilateral coxarthrosis the cases with radiographic signs of progression had 3 years longer average interval than in the remaining 13 stationary cases (Fig 7) Of 31 cases reviewed after periods up to 10 years 20 had deteriorated compared with 17 of the 19 reviewed after a long interval

Only 4 of the bilateral cases had been reviewed after 15 to 22 years All 4 showed heavy radiographic progress average 5 2 points (range 5-8) Of the 13 cases who had not progressed the interval was less than 5 years in 6 between 5 and 10 years in 4 and 10 to 15 years in 3 The average for all 13 cases was 6 4 years

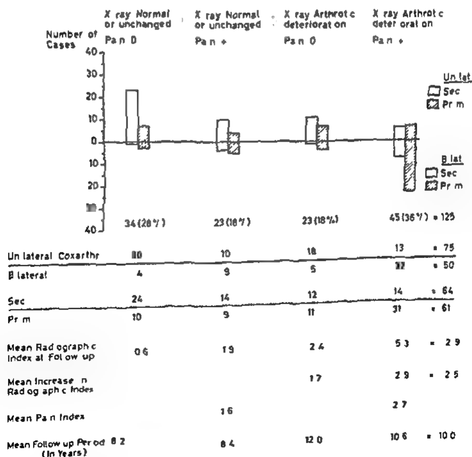
Comments

In the unilateral cases the incidence of radiographic changes appeared to have increased more than their severity while in the bilateral cases radiographic severity had increased steadily with time (Table XII)

Hohman in his series (cf p 38) found an incidence of 10% at review from 1 to 2 years and 45% after 6 years or more The incidence in the present material was 10 of 35 cases reviewed after 2 to 6 years and 58 of 90 cases reviewed after a longer period

d Frontal Position of Fused Hip

Eighty seven (70%) of the probands had various degrees of abduction (>5) from the neutral angle The average degree and incidence of radiographic deterioration was slightly higher in the abducted position than in adduct on or the neutral position (Table XV) but the difference was not statistically significant The ratio of unilateral and bilateral cases in the three position groups was adduction 1 4/1 neutral 1 5/1 and abduction 1 5/1 Thus the same proportion in all three groups



Of Danielssons's material one third showed no progression and in 8 hips signs of regression were observed Of the 50 bilateral cases of the present material one fourth showed no signs of progression but in no instance were signs of regression observed

The difference in radiographic deterioration of the mobile hip in the present 36 bilateral, primary cases (2.6 $\pm$ 0.12) and Danielsson's 104 hips (1.7 $\pm$ 0.13), followed up on the average 11 years after a diagnosis of primary coxarthrosis had been made, was significant***

c. Interval Between Operation and Review

The interval was on the average the same for primary and secondary cases (10 years)

In unilateral coxarthrosis the average interval was over 3 years longer for the cases in which degenerative signs had appeared (Fig 7) Of the 43 cases where the interval was less than 10 years, 14 displayed signs of deterioration compared with 17 of the 32, reviewed after a longer interval (Table XI).

Fig 7 Incidence and Degree of Radiographic Deterioration and Pain

were observed in only 5 of the 24 probands reviewed up to 8 years after the operation. The fact that half of the unilateral and four fifths of the bilateral cases were found to have deteriorated by the time of review, more than 5 years after operation, and that the radiographic deterioration was more severe than in a comparable unoperated series (Danielsson 1964), and the absence of radiographic signs of regression, did not suggest unburdening of the mobile hip.

Training the arthrodesed subject to load the fused leg has been suggested by authors who at review had found that many of their cases had developed arthrosis and/or pain in the mobile hip (Leger 1956; Hohman 1962; Mach 1964, Demigneux 1967). It can hardly be expected however that such a measure would permanently affect their standing habits Standing is largely an unconscious effort as long as it does not incur discomfort or pain With easy, energy saving standing restricted to one side the arthrodesed subject will as a rule automatically exploit the pain-free, mobile leg for this purpose. Furthermore, biological factors and the forces acting on the joint during gait, are bound to be more important for the fate of the mobile hip than static strain

The compensatory demands on the mobile hip during walking are well documented (Steindler 1955; Seevald and Debrunner 1964; Casuccio 1964, Ducroquet 1965). The only way the fused leg can be swung forward is by way of the pelvis with the mobile hip as a pivot. This occurs during the stance phase of the mobile leg when the joint is being loaded with at least twice the body weight as the pelvis tilts and rotates around the femoral head It is reasonable to expect that such compensatory exertion hastens the degeneration of any joint not biologically fit and congruent It may be argued that the stiffness of the fused hip before the operation had placed similar demands on the mobile hip But as a successful arthrodesis leads to a more active life, the compensatory strain on the mobile hip will still be increased.

Other mechanical factors of probable importance for the fate of the mobile hip were, a) loss of suppleness of the gait as the remaining, normal segments of the extremity can only partially compensate for the loss of the hip joint, pelvic tilt and rotation being important factors in decreasing the vertical displacement of the center of gravity of the body (Saunders, Inman and Eberhart 1953); b) reduction of the contact area in the mobile hip due to the commonly occurring inclination of the pelvis toward the fused side (Pagani, Morosini and Buratti 1967) and c) walk-way studies have shown that the stance

Average Degree	1.3 (2 2)	1.1 (2.4)	1 7 (2.8)

Comments

The abducted position of the fused hip was for a long time recommended to compensate for shortening of the leg The rationale was, that when such shortening was marked this source of compensation could be utilized for obviating unsightly aids, for providing better feeling of contact with the ground ("Bodengefuhl, Machacek 1956) and facilitate walking and standing without shoes

The adverse effects of marked abductions have since been well recognized however and corrective osteotomies have not infrequently been reported (Hauge 1963) In the present material 3 such late osteotomies had been preformed The abducted position of the hip renders the gait awkward and requires circumduction of the fused leg in the swing phase, and an increased strain is thrown on the back and the mobile hip during walking and standing, with time entailing a risk of degenerative changes with symptoms (Fürmaier 1959, Hohman 1962, Seevald and Debrunner 1964 and Demigneux, Rainaut and Cedart 1968)

The fact that radiographic deterioration, even though only slight was largest in the abducted position, suggests that this may have been a contributory factor

Discussion

Radiographic signs of arthrotic deterioration of the mobile hip

were observed in only 8 of the 24 probands reviewed up to 5 years after the operation The fact that half of the unilateral and four fifths of the bilateral cases were found to have deteriorated by the time of review more than 5 years after operation, and that the radiographic deterioration was more severe than in a comparable unoperated series (Danielsson 1964), and the absence of radiographic signs of regression, did not suggest unburdening of the mobile hip

Training the arthrodesed subject to load the fused leg has been suggested by authors who at review had found that many of their cases had developed arthrosis and/or pain in the mobile hip (Leger 1956, Hohman 1962, Mach 1964, Demigneux 1967) It can hardly be expected however that such a measure would permanently affect their standing habits Standing is largely an unconscious effort as long as it does not incur discomfort or pain With easy, energy saving standing restricted to one side the arthrodesed subject will as a rule automatically exploit the pain-free, mobile leg for this purpose Furthermore, biological factors and the forces acting on the joint during gait, are bound to be more important for the fate of the mobile hip than static strain

The compensatory demands on the mobile hip during walking are well documented (Steindler 1955, Seevald and Debrunner 1964, Casuccio 1964, Ducroquet 1965) The only way the fused leg can be swung forward is by way of the pelvis with the mobile hip as a pivot This occurs during the stance phase of the mobile leg when the joint is being loaded with at least twice the body weight as the pelvis tilts and rotates around the femoral head It is reasonable to expect that such compensatory exertion hastens the degeneration of any joint not biologically fit and congruent It may be argued that the stiffness of the fused hip before the operation had placed similar demands on the mobile hip But as a successful arthrodesis leads to a more active life the compensatory strain on the mobile hip will still be increased

Other mechanical factors of probable importance for the fate of the mobile hip were, a) loss of suppleness of the gait as the remaining, normal segments of the extremity can only partially compensate for the loss of the hip joint, pelvic tilt and rotation being important factors in decreasing the vertical displacement of the center of gravity of the body (Saunders, Inman and Eberhart 1953), b) reduction of the contact area in the mobile hip due to the commonly occurring inclination of the pelvis toward the fused side (Pagani, Morosini and Buratti 1967) and c) walk-way studies have shown that the stance

phase on the fused side is diminished and prolonged on the mobile side (Seevald and Debrunner 1964) or on the 'good side in limping (Rydell 1966)

Other factors of possible importance were age at operation (within the etiological groups), sex body weight and occupation No appreciable influence of these factors could be discerned

3 *Conclusions*

Incidence of radiographic deterioration of the mobile hip in the present material was similar to that found in comparable, published series The severity of radiographic deterioration in the bilateral cases, was however significantly higher than in Danielsson s series of unoperated cases, with the same average follow-up interval

Arthrodesis of the hip was generally well tolerated by the contralateral hip provided the latter was free from changes at the outset and *the susceptibility associated with the primary form of coxarthrosis*

The professed relief of the mobile hip, when slightly or moderately affected, was not sustained by the findings of the present investigation as with time the majority of these cases showed heavy increase in radiographic severity The high rate of deterioration in bilateral coxarthrosis, particularly the primary form, strongly indicated that the fate of the mobile hip was dependent primarily on biological factors i e its ability to withstand the mechanical surcharge thrown upon it On the other hand, the fate of the hip was not found to vary appreciably with such factors as sex occupation or body weight

It was concluded that the increase in radiographic severity in the present material compared with *that of Danielsson s series*, refutes the hypothesis that arthrodesis results in mechanical relief of the mobile hip

C Clinical Examination

1 Pain in Mobile Hip

a Incidence

Sixty eight probands had pain in the mobile hip at follow-up (not to be confused with the 68 probands with arthrotic deterioration) Twenty-one had had pain also before the operation Of the latter, 10 had become worse, 8 were unchanged and 3 had less pain than before Thus half of the probands had either developed pain or become worse The incidence of pain was significantly higher in the bilateral cases*** (Fig 7)

b Severity

At follow-up 35 probands had mild 21 moderate and 12 severe pain in the mobile hip (cf p 19) In two thirds of the painful hips radiographic severity had increased Degree of pain was significantly higher in these than in the remaining third with no increase*** (Fig 7) The average increase in radiographic severity was three times as large in the 33 hips with moderate or severe pain as in the 35 hips with mild pain

Of 43 overweight probands 21 had pain in the mobile hip Average severity of pain in these was the same (2 4 index points) as in the remaining 47 hips

c Relation to Range of Motion

Thirty-one of the mobile hips had less than 90 degrees of flexion and all but one of these had a flexion contracture Twenty-eight of these had shown radiographic changes at operation and 23 had since progressed

In all 35 probands had a flexion contracture in the mobile hip, average 21 degrees (range 10 -65) Thirty of these hips had shown changes at operation Twenty-nine of the 35 probands had pain in the mobile hip with an average score of 2 8 index points

Comments

Degel (1957) reviewed 115 arthrodesed cases from 3 to 8 years after operation In thirty-nine (34%) the mobile hip had become pain-

ful or worse, it was unchanged in 61 and had become painless or better in 10.

Of 75 cases subjected to arthrodesis Hohman (1962) found that the mobile hip had become painful or worse within 1-7 years in 37%.

In the present material the incidence found at review within 10 years of the operation was the same as in the above two series, namely 27 of 74 cases (average, 2.6 index points). The corresponding figures for those examined after a longer period were 30 of 51 (average, 2.2 points).

In his unoperated series, Danielsson (cf. p. 41) found no relation between pain and etiology of the disease or sex. Two thirds of the hips in his series had become less painful during the follow-up period. In contrast, in half of the present material the mobile hip had become painful or worse*** (Table XVI)

Table XVI. Incidence of Pain in the Present Material compared with Danielsson's Series (1964)

Degree of Pain	Danielsson (1964)			The Present Material		
	Male	Female	Total	Male	Female	Total
Developed Pain (or More Severe)	10	10	20	19	38	57
Unchanged	3	11	14	2	6	8
Less Severe	28	42	70	2	1	3
Always Painless	11	4	15	25	32	57
Total	52	67	119	48	77	125

At the time of diagnosis all the hips included in Danielsson's series had structural and/or joint space changes. For comparison, 27 of the present 43 hips, with such changes at operation, had become painful or worse. The average age in Danielsson's series was 10 years higher in primary and 6 years higher in secondary coxarthrosis This may have played some role as the amount of activity and work are likely to be less in the higher age groups.

Danielsson also studied the correlation between the severity of pain and contractures in various planes in 123 hips. He found that this correlation was strongest for flexion contracture. In the present material two thirds of the moderately or severely painful hips were found among the 35 with flexion contractures.

2. Working Capacity

At the time of operation 12 probands already had a pension, 8 because of age and 4 because of disability. In the remaining 113 cases one of the chief goals of the operation was to restore working capacity. Of the 113 cases, 21 were granted an old age (5) or disability (16) pension within 3 years after operation and never resumed working. Of the 92 cases who resumed work, 56 were females and 36 males.

Return to the same type of work as before operation was more common among those who had light occupations than among those with "moderate" or "heavy" work (Table XVII). Two thirds of those who returned to their former occupation had been operated upon for unilateral coxarthrosis (Table XVIII).

Table XVIII Working Capacity After Operation

Working Capacity After Operation	Unilateral Cases		Bilateral Cases		Total
	Primary	Secondary	Primary	Secondary	
Resumed working after op					
Same work as before op	7	32	12	8	59
Lighter work than before	11	11	8	3	33
	18	43	20	11	92(74%)
Unable to resume work					
Disability Pension	4	3	8	1	16
Age Pension	—	1	4	—	5
	4	4	12	1	21(17%)
Pensioned before op					
Disability Pension	1	1	1	1	4
Age Pension	2	2	3	1	8
	3	3	4	2	12(9%)
Total	25	50	36	14	125(100%)

Of the 113 cases, 69 had unilateral and 44 bilateral coxarthrosis at the time of operation. Of the former, 61 returned to some form of work, against 31 of the latter.

The interval between operation and resumption of work ranged from 3 months to 2 1/2 years, average 11.5 months. The average interval did not vary with category of work. It was 11.8 months in the 61 unilateral cases and 10.8 months in the 31 bilateral cases. It was on the average 10.4 months for males and 12.1 months for females. (fig 8)

Table XVII. Type of Work before and after Operation. Probands not granted Pension at the Time of Operation

Type of Work Before Operation	Number	Work after Operation				
		Heavy	Moderate	Light	Slight	None
Heavy	26	10	4	6	1	5
Moderate[1)]	43		16	10	9	8

1) E.g. factory work, all work in large household (≥4 persons), all work in small household (<4 persons) + extra work.

2) E g all work in small household, light manual labour

3) E.g. all work in small household except cleaning, clerical work

Types of Work Represented

Males (42)

Heavy — Farmer or farm labourer (10), construction worker (5), unskilled labourer (4), factory worker (3), mason (2), forester (1), well digger (1)

Moderate — Industry worker (2), butcher (1), baker (1), cooper (1), house cleaner (1), electrician (1), wholesaler (1), news-stand salesman (1), automobile reparator (1)

Light — Electrical technician (1), engineer-salesman (1), bicycle mechanic (1)

Slight — Director (1), light industry worker (1), clerk (1)

Females (71)

Heavy — None

Moderate — Housewife (5), housewife + (house-cleaning farming, saleswoman, gardener, librarian, secretary)(24), waitress (2) house-cleaner (1), home-worker (1)

Light — Housewife (18), housewife + (bookkeeping, shop assistant)(2), sales manager (1), part-day nurse (1)

Slight — Housewife (8), clerk (2), managing director (1), part-time shop assistant (1), secretary (1), maid (1), teacher (1), fur seamstress (1)

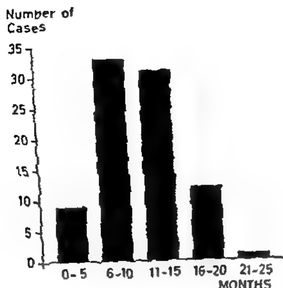

Fig 8 Interval Between Arthrodesis and Resumption of Work in 92 Cases

Sixty four probands were pensioners by the time of the review. Thirty-one were receiving an old age pension and 33 a disability pension.

Of the 31 probands who were receiving an old age pension, [illegible] had been pensioners already before the operation, [illegible] within 3 years of the operation and had not resumed work and the remaining 18 had reached retirement age after having worked from 2 to 18 years, (average 6.6 years) after the operation Of the 31 probands, 22 had been operated upon because of primary coxarthrosis (Table XIX).

Of the 33 probands who were granted a disability pension, 4 had been pensioned off before the operation, 16 within 3 years of operation and had not resumed work, and a further 13 after having worked for 1 to 20 years, (average 6.4 years) after operation. Of the 33 probands, 23 had been operated for primary coxarthrosis (Table XIX).

Of the 61 probands still working at the time of the review, 46 were still engaged in the same occupation as before operation (Heavy 5, Moderate 13, Light 15 and Slight 13), whereas 15 had taken up lighter work. Six of the 61 probands were receiving a partial disability pension. Over half of these 61 probands had been operated upon be-

	12		21		18					13					61					125

cause of unilateral secondary coxarthrosis (Table XIX)

In primary coxarthrosis the most common reason for a disability pension was pain and/or stiffness of the mobile hip Seventeen of the 23 primary cases had been granted a disability pension for this reason Five of the 10 secondary cases had been granted a disability pension because of pain and/or stiffness of the mobile hip Common associated causes in both categories were obesity, cardiac trouble, a protracted postoperative course, sometimes with reoperations, symptoms referable to other joints (back and knees) and mental depression In some cases difficulties in finding suitable work was probably a contributary factor

Comments

Working capacity is at least temporarily frequently improved or restored after arthrodesis of the hip The frequency with which this occurs depends on a number of factors, such as age, general health type of work etc (Karlen 1944, Mayr 1954 and Acchiapati 1962)

In the present material the chief difference in this respect was found between probands operated for secondary and primary coxarthrosis Working capacity was improved more often and was more lasting among the former Disability pension had since the operation been granted to 8 (12%) of the former and 21 (34%) of the latter**

3 Restriction of Function

By assessing and grading some important daily activities, the degree of restriction of function in different parts of the series was compared (Table XX)

Walking Distance The probands assessment of their walking capacity was found to reflect their general functional capacity Thus, the 62 who stated that they could walk over 1 5 kilometres had a far better over all functional capacity than the remaining 63 (Fig 9 Table XXI)

Twenty probands (16%) thought that they had recovered their walking capacity after the operation. 14 had been fused for unilateral and 6 for bilateral coxarthrosis Only in 3 of the 20 cases were radiographic signs of progress in the mobile hip demonstrable

Thirty six probands (29%) claimed pain in the mobile hip to be the main cause of reduced walking ability The index of radiographic

50 Bilateral Cases 7 2 Points 61 Primary Cases 7 5 Points

severity at the review was, on the average, 4.8 index points for these 36 hips, with an average increase in index of 2.5 points. The pain index was 2.8 points.

Of the 63 probands who could only walk less than 1.5 kilometres, 52 had pain and/or showed radiographic progress in the mobile hip. Reduced walking capacity was significantly more common among the bilateral cases*** (Table XXI)

Walking Outside. Most of the 49 probands that used one stick carried it in the hand on the operated side. For the 58 probands who could walk unaided, arthrotic progress was, on the average, 0.6 index point, for the 49 using one stick, 1.9 points, for the 13 using two sticks, 3.0 points, and for the 5 probands using two trestles, 1.0 point That the progression among the 5 last probands using trestles was so slight was explained by the fact that only one of them used trestles because of symptoms in the mobile hip, whereas the rest used them mainly for balance outdoors. The latter 4 probands had markedly reduced mobility of the ipsilateral knee, one of which was ankylotic as a result of an intraarticular fracture.

Only 35 probands stated that walking on snow or in slippery roads was not difficult whereas 65 had difficulties and 25 never went out alone in such weather Twice as many probands had difficulties in walking uphill (78) as downhill (34) and 13 could manage neither.

Stairs Most of the probands had no difficulty in walking up or down stairs Theoretically, the smaller the angle of flexion in the fused hip the more difficult it is to climb stairs. In the present material no such correlation was found Thirty-eight probands had trouble getting on a bus or a train and 19 could not do so without help.

Difficulties in getting into a car were common (43 probands) and many could only get in from one side, i.e. with the mobile leg first. Some of the probands always had to sit in the front seat in order to have enough room for the stiff leg.

Toilet Seventy per cent of the probands could manage without much difficulty. One third of the total number of probands used a heightened toilet seat and 20 had put handles on the wall to facilitate sitting down and rising from the toilet.

Twenty-four of the females had difficulties when passing urine. Thus, 21 were troubled by urine running down the stiff thigh and 9 of these plus 3 others were troubled by the stream of urine tending

Table XXI Comparison between 62 Probands with Walking Capacity of 1 500 metres or more and 63 Probands with less.

the operation Many daily activities could be mastered only with difficulty and some had since the operation become unsurmountable obstacles, especially for the elderly probands Stiffness of the fused hip, in association with pain in other joints, particularly the mobile hip, were the most common reasons for all degrees of disability

5 Conclusions

Arthrodesis of the hip proved to be an effective method of eliminating the invalidity caused by pain and contractures in the arthrotic joint As a measure of this fact three fourths (92) of the probands had been able to resume work, most (59) of whom had returned to their former occupation

However, arthrodesis of the arthrotic hip is generally performed in the latter half of life when adaptability to changed conditions has become decreased. Consequently, probands with the primary form of coxarthrosis, particularly when bilateral, showed far less good functional results and the lowest rate of restored working capacity, whereas the opposite was true of probands with secondary coxarthrosis especially those with unilateral affection

It was concluded that as functional capacity after arthrodesis of the hip was largely dependent on age and painfree, compensatory motion of adjoining joints most important of which was the mobile hip the total functional gain was often of a temporary character

to run in front of the toilet bowl. For 19 of the women these difficulties were constant and quite distressing Some of them always carried a plastic container in their bags when away from home to prevent embarrassment. Seven of the total number of probands had not been able to use a toilet seat heightener and three had ever since the operation used the toilet in a standing positon

Dressing Except for socks and shoes, dressing was not difficult for 98 (78%) of the probands

Putting on sock and shoe on the operated side proved to be an obstacle for nearly all of the probands This was frequently solved by the help of another person or by the use of special aids Only four probands could tie the shoelace on the fused side

In addition to socks and shoes, putting on trousers was the commonest difficulty Many had learned to use special aids or their walking sticks upside-down as a hook to make this task easier Daily dressing time was assessed to be normal for 39 probands (2-5 min prolonged for 57 (5-10 min) and markedly prolonged for 29(>10 min)

Bathing Eighty three probands (66%) had more or less difficulties when taking a bath Thirty-five were dependent on help whereas others assumed a kneeling position or had special seats made for the bath Still others had replaced the bath by a shower All were dependent on help for cutting townails on the fused side

4 Discussion

In coxarthrosis loss of function is caused by pain faulty positions and decrease in range of motion By arthrodesis two factors are permanently abolished at the price of eliminating what useful motion there may have been left in the joint But one of the paradoxes of arthrodesis of the hip was the fact that its first goal i e complete abolishment of motion in the joint in order to increase the overall functional capacity of the individual imposed serious restrictions on his pursuits

Most of the probands who before the operation had been on the brink of permanent invalidity were glad to have sacrificed the remaining motion in the joint to obtain freedom from pain For others the completeness of the stiffness had come as a shock and some of the probands had a period of mental depression after discharge when faced with the tasks of daily living, and a few still bitterly regretted

C Methods

The investigation comprised a registration of the static support pattern, a comparative study of preoperative and follow-up radiograms of the mobile hip and a clinical examination

The static support test was performed with the aid of two electronic scales, one for each foot, which were calibrated to the weight of the proband The difference in loading between the two scales during a certain period could then be calculated from the tracings on an ink-writer The purpose of the test was to ascertain the static support pattern in free and in instructed modes of standing (cf p 13) The test lasted for 20 minutes

The radiographic examination comprised radiograms of the hips, pelvis lumbar spine and knees The chief aims of the radiographic examination were a) to assess radiographic signs of arthrotic deterioration of the mobile hip by a comparison with the preoperative radiograms according to a numerical index (Table IV), and b) radiographic determination of the degree of ab- or adduction of the fused hip

The clinical examination aimed chiefly at recording a) range of motion and degree of pain in the mobile hip, b) degree of flexion of the fused hip, c) state of lumbar spine and knees and d) the probands' accounts of their ability to perform daily activities and of their working capacity

Chapter III RESULTS

A Static Support Test

The test showed that when standing easy for 10 minutes only 15% of the probands used the fused leg for support (> 60% f 1) whereas both legs were loaded fairly evenly (40%-60% f 1)by 43% and the mobile leg was used for support by 42% of the probands

There was a distinct difference in the support pattern according to the state of the mobile hip Thus, arthrotic changes and pain were significantly more prevalent in the cases with equal support and those who preferred the fused leg for support than in those who preferred the mobile leg Further loading of the fused leg appeared to be facilitated by the neutral and adducted position of the fused hip and by shortening of the fused leg

IV SUMMARY

Chapter I INTRODUCTION

Since the beginning of the century arthrodesis has been one of the leading methods used in the surgical treatment of coxarthrosis According to many authors, arthrodesis of one hip in bilateral coxarthrosis provides the patient with a supporting leg so that the mobile hip is correspondingly relieved from mechanical strain

The aims of the investigation were to find a) to what extent the fused hip was used for static support, b) the incidence, rate and degree of radiographic deterioration of the mobile hip and c) the incidence and degree of pain in the mobile hip and the influence of pain on daily activities and working capacity

Chapter II MATERIAL AND METHODS

A Classification

The cases were classified as unilateral or bilateral coxarthrosis on the basis of preoperative radiograms Distinction between primary and secondary coxarthrosis was based on the history and on radiographic appearance

B Material

The investigation was based on a follow-up examination of 125 probands who had undergone arthrodesis of the hip 2 to 22 years previously (average 10 years) for unilateral or bilateral coxarthrosis in the two forms of the disease the primary and secondary

There were 77 females and 48 males The average age was 52 years at the time of operation and 61 at the review It was the same in both sexes In 61 cases with primary coxarthrosis, mainly bilateral, the average age at the review was 66 years, and in 64 with secondary coxarthrosis, mainly unilateral, 57 years

in a joint initially affected On the basis of these findings and in comparison with Danielssons's (1964) series of unoperated cases (cf p 42), the prognosis of the mobile hip in bilateral coxarthrosis, especially of the primary type, was considered poor

C Clinical Examination

The working capacity and gross functional capacity was often improved or restored after healing of the arthrodesis Ninety-two (74%) of the probands were able to resume work, 59 (47%) in their former occupations

The extent and permanency of recovery was dependent on the state of other joints, especially the other hip, and on the proband's age Consequently probands with the primary form of coxarthrosis, particularly when bilateral, showed far less good functional results and the lowest rate of restored working capacity, whereas the opposite was true of those with secondary coxarthrosis, especially in unilateral affection

It was concluded that as long as the hip arthrodesed subject was relatively young with no other joints affected the adverse effects of the arthrodesis were more easily neutralized In the older age groups, particularly in primary coxarthrosis, the combined effects of advancing age and changes in the opposite hip frequently caused an early diminution of the functional gain achieved

The instructed modes of standing showed that 90% of the probands could use either leg for support for a period of 2 minutes whereas nearly one third of the probands could not distribute body weight evenly between the legs for a period of 5 minutes Even loading of both legs was rendered more difficult by large discrepancies in leg length

The support pattern in Romberg's test revealed that most of the probands resumed their support pattern displayed in the first part of the test

As regards the leg generally used for support in daily life, the findings were in agreement with the opinion of 75% of the probands Those whose opinion differed from the results showed no preference for either leg

Compared with what may be considered normal, the number of shifts was markedly small, especially among those who showed a distinct preference for uneven loading

It was concluded that the fused leg was generally not used for chief support in standing and did not afford relief of the mobile hip The great majority of the probands had loaded mainly the mobile leg as long as it could be comfortably used for this purpose

B Radiographic Examination

The radiographic examination revealed signs of arthrotic deterioration of half of the mobile hips and that the prognosis of the mobile hip was not uniform

A marked difference, depending chiefly on two factors, was observed, i e whether or not the mobile hip was initially affected with arthrotic changes and whether the other hip had been fused for primary or secondary arthrosis This strongly suggested that the dominant factor deciding the future of the mobile joint was of biological nature Thus, the mobile hip fared best in the absence of the above factors and by far worst in the presence of both

The frequency and severity of radiographic changes in the mobile hip, when initially affected, did not suggest relief of its weight bearing functions by the fused hip Far from being unburdened by the fusion of the opposite hip the mobile hip was subjected to heavy compensatory strain under both static and dynamic conditions which with time generally resulted in degenerative changes in the joint when biologically susceptible In no instance were signs of regression demonstrable

INTRODUCTION

Although samples of patients with peripheral arterial insufficiency chosen by different methods and with different criteria have been described, no attempts have been made to relate the frequency of these diseases to the population at risk PERLOW (1962) stated "Although most people over 60 years of age have some degree of arteriosclerosis, no statistics are available on the number who have circulatory impairment in the lower extremities" Arteriosclerotic changes are becoming more frequent with increasing age (STERNBY 1968) SOUTH et al (1957) thought that the observed increase of pathological changes in the arteries was caused by increasing survival in the population and he felt that after the age of 70 almost everybody had degenerative arterial disease

Also, arterial changes in conjunction with diabetes mellitus have been studied and KRAMER and PERILSTEIN (1958) claimed that these conditions have increased between 1921 and 1956 On the other hand BELL (1957) found that the incidence of gangrene in diabetes mellitus decreased during the first half of this century

It has been suspected that the true incidence of arteriosclerotic changes in the lower limbs is increasing In the Department of Orthopaedic Surgery in the General Hospital, Malmö, the proportion of patients treated for peripheral arterial insufficiency as well as the number of beds occupied by these cases have increased

However, this is not sufficient evidence of a true increase in the incidence of this disease All hospital facilities in the city as well as changes in the distribution of the population at risk would have to be included in a survey of incidence changes Malmö has previously proved to be suitable for epidemiological studies as demonstrated by BIORCK (1955), HALL (1961), SIEVERS (1963), ALFFRAM and BAUER (1962), ALFFRAM (1964) BERGE

INTRODUCTION

Although samples of patients with peripheral arterial insufficiency chosen by different methods and with different criteria have been described, no attempts have been made to relate the frequency of these diseases to the population at risk. PERLOW (1962) stated "Although most people over 60 years of age have some degree of arteriosclerosis, no statistics are available on the number who have circulatory impairment in the lower extremities." Arteriosclerotic changes are becoming more frequent with increasing age (STERNBY 1968). SOUTH et al. (1957) thought that the observed increase of pathological changes in the arteries was caused by increasing survival in the population and he felt that after the age of 70 almost everybody had degenerative arterial disease.

Also, arterial changes in conjunction with diabetes mellitus have been studied and KRAMER and PERILSTEIN (1958) claimed that these conditions have increased between 1921 and 1956. On the other hand BELL (1957) found that the incidence of gangrene in diabetes mellitus decreased during the first half of this century.

It has been suspected that the true incidence of arteriosclerotic changes in the lower limbs is increasing. In the Department of Orthopaedic Surgery in the General Hospital, Malmö, the proportion of patients treated for peripheral arterial insufficiency as well as the number of beds occupied by these cases have increased.

However, this is not sufficient evidence of a true increase in the incidence of this disease. All hospital facilities in the city as well as changes in the distribution of the population at risk would have to be included in a survey of incidence changes. Malmö has previously proved to be suitable for epidemiological studies as demonstrated by BIÖRCK (1955), HALL (1961), SIEVERS (1963), ALFFRAM and BAUER (1962), ALFFRAM (1964), BERGE

(1967) and STERNBY (1968) dealing with problems ranging from rheumatic fever and coronary disease to fractures, cancer and atherosclerosis

The objective of the present study was to calculate age and sex specific incidence for the major groups of conditions leading to peripheral arterial insufficiency and to study possible changes over a 17-year period Against the background of the hospital facilities in the city it should also be possible to estimate some socio economic implications of this group of diseases

MATERIAL AND METHODS

THE CITY OF MALMÖ

The city of Malmö the third in population in Sweden [redacted] a center of industry and trade From the end of 1948 to the end of 1965 the population increased from 185 947 to 249 161 [1] the increase being comparatively steady over the years (Table 1)

Table 1 *The population of Malmö 1948—1965*

	Men	Women	Total
1948	87 635	98 312	185 947

HOSPITAL FACILITIES

In the city of Malmo almost all hospital facilities are owned by the community and financed by city and state funds including the compulsory state health insurance On the whole, there are very few private or voluntary hospitals in Sweden and these only in the large cities In the city of Malmo there are two private nursing homes with altogether 37 beds and facilities for the care of simple cases of chronic disease

Hospitalization is free of charge except for the care of chronic somatic disease where after six months of hospitalization a small sum, well within the limits of the general pension, is charged

The city constitutes a defined area for health care with a central administration for the three municipal hospitals *Malmo Allmänna Sjukhus* (MAS) for mainly emergency and short time somatic disease, Värnhems Sjukhus (VAS) for chronic somatic disease, and Malmo Östra Sjukhus (MÖS) for mental disease MAS is a teaching hospital affiliated to the

CHAPTER 4

RESULTS

4 1 *Premises*

The typical reactions which occur in medullary cavity, cortex and periosteum following an intramedullary intervention have been described in detail in chapter 2 The same reproducible histological changes were observed also in our material, and need not be discussed in detail again in this chapter

In this discussion of results, emphasis will be placed on a *comparison* of the changes observed in the various groups In all cases sections of the treated femur were also compared with those of the control femur Since no measurements were made, the observations are only graphic and descriptive, and not suitable for statistical analysis

The histological sections provided the basis for the material studied All other investigations were complementary and helped to confirm the observations made on the histological material To avoid repetition, the entire histological material, including the fluorescence-microscopic findings, will be collectively discussed in sections 4 3 and 4 4 An exception will be made for the animals studied by sequential fluorochrome labelling during 7 weeks (sections 4 6 and 4 7)

In the Goldner-stained sections the distribution and intensity of stained osteoid varied from section to section Sometimes the osteoid was stained in one animal but not in the other On the whole, the data obtained provided too little constant information to warrant definite conclusions A detailed discussion would be detrimental to the surveyability of this documentation

It was also found that longitudinal sections C (fig 11) supplied no new information, shortly after the start of the ultimate experiment, therefore, section C was used for making transverse sections

Since no essential differences in the reaction pattern of cortex, medullary cavity and periosteum were observed in the material from groups 3A (commercial acrylic cement Palacos) and 3B (commercial acrylic cement *Sulfix-6), the two groups will be discussed under the joint heading* group 3 RS + PMMA The same applies to groups 4A and 4B, which

will be discussed under the joint heading group 4 RS + PMMA without catalyst

The photomicrographs shown are representative of the group and observation period concerned

The photomicrographs of histological sections shown in this section depict haematoxylin-eosin (HE) stains The photomicrographs were made with the Leitz Orthomat on Scientia film 50-B-65 A green filter 546 nm was used in the exposures The periosteum is always shown at the top of the photograph and details are viewed from the endosteal cortex side The legends to the figures mention in succession observation period group femur involved rabbit number, segment number (A B C or D) and if necessary type of cement
Pa (= group 3A commercial Palacos)
Su (= group 3B commercial Sulfix-6)
Pa–C (= group 4A Palacos without catalyst)
Su–C (= group 4B Sulfix-6 without catalyst)

To summarize the groups to be discussed in the following sections will be referred to as

group 1 reaming (R) and suction (S)
group 2 RS + Palacos Rod
group 3 RS + PMMA
group 4 RS + PMMA without catalyst
group 5 RS + modified Sulfix 6 with CMC gel

4 2 *Macroscopic findings*

Apart from a sligthly larger diameter as compared with the control bone, the deep-frozen femurs showed no relevant changes Near the lateral femoral condyle at the site of the vent hole, some callus tissue was usually found The distal cut surface was chosen in such a way that this callus tissue did not fall in the most distal sector (D) Once the femurs were cut into sections it was invariably found that the acrylic cement always filled the entire medullary cavity *and* was always fixed firmly to the bone, regardless of the type of cement used *This did not* apply to the loose fitting rods in group 2, these, however, were encapsulated by regenerated bone marrow

4 3 *The normal histological features of the other femur used as control*

The normal histological features of the transverse section of the control femur show, throughout the specimen, osteons with vital osteocytes

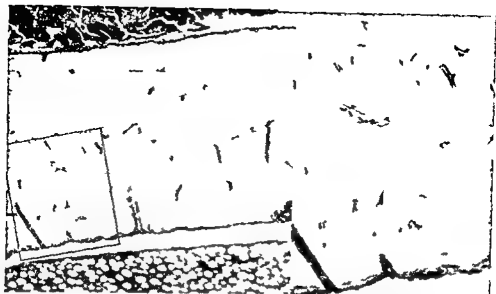

Fig 12 Normal features of the cortex – R 6561 B (HE x 40 detail x 95) A thin lamellar layer of endosteal bone is demarcated by a cement line from a central zone made up of primary and secondary osteons Lamellated bone is also *seen on the periosteal side with several cement lines indicating that the cortex has* locally increased in diameter as a result of appositional growth No woven bone is seen anywhere A layer of regularly spaced flattened cells is seen in the endosteum The periosteum consists of an inner osteogenic layer and an outer fibrous layer

regularly distributed over the cortex (fig 12) A layer of regularly spaced flattened cells is found in the endosteum Since the microscopic architecture of a bone can be regarded as a cumulative product of its own growth and remodelling the cortex itself shows at several sites of the diaphysis many varying combinations of the structural patterns (Enlow 1968) The *trilaminar structure shown in fig 12 is one of the variations which can be encountered in cortical diaphyseal bone and cannot be described as a typical structural pattern* The figure has been chosen however because the diaphyseal cortex is usually made up of superposed zones of different types of bone tissue rather than of a single layer The fluorescence sections show moreover that diaphyseal growth normally takes place in transverse direction by formation of lamellated bone on the periosteal surface while endosteal resorption alternates with lamellated bone apposition (cf section 4 6)

4 4 *Histological findings (combined with fluorescence microscopy)*

Observation period 1 week

In *group 1* one eighth to one fourth of the endosteal cortex shows

signs of necrosis The bone lacunae are often empty The nuclei are sometimes swollen and the cement lines show a sharper circular definition around the bone lacunae, resembling an onion skin configuration Occasional resorption lacunae appear The endosteum is usually lacking, but in a few places a thin new endosteal layer has been deposited The latter is confirmed in the fluorescence section by the presence of Alizarin Red S on the endosteal surface The periosteum is thickened and a thin subperiosteal layer of woven bone has been deposited, in which many Micropaque-filled vessels are visible

The medullary cavity contains old blood which shows incipient organization Dead fragments of bone, detached as a result of the drilling, are also found in the medullary cavity New medullary Micropaque filled blood vessels are already visible

The sections of *group 2* show approximately the same features as those of group 1 A thin necrotic endosteal layer is again in evidence, the subperiosteal reaction is slightly more pronounced, and in the medullary cavity the intramedullary rod the contours of which are clearly defined, is occasionally already surrounded by new bone marrow There are new medullary vessels

In *group 3* the cortical necrosis is much deeper and involves one half to two-thirds of the cortex, counting from the endosteum There are occasional areas of less extensive necrosis Not one vital cell is left in the endosteum A few smaller resorption lacunae are localized in the middle zone of the cortex The periosteum has markedly increased in thickness and contains many Micropaque filled vessels The subperiosteal layer is considerably thicker than that in groups 1 and 2 The medullary cavity is translucent (the acrylic cement is dissolved)

In *group 4* the cortex is necrotic over nearly its entire width Only a very narrow zone of the outer part of the cortex contains an occasional vital cell The periosteum shows marked reactive thickening and is highly vascularized, the new layer of subperiosteal bone is about twice as thick as that in group 3 The medullary cavity is again translucent

In *group 5* the endosteal part of the cortex again shows necrosis, but much less extensive than that in group 3 and certainly less than that in group 4 The features are more reminiscent of those in groups 1 and 2, but at some sites the necrosis is slightly more extensive The subperiosteal reaction too is somewhat more pronounced than that in groups 1 and 2 Again there is marked vascularization The medullary cavity contains fragments of dead bone and debris, no blood vessels being visible

Observation period 2 weeks

In *group 1* the extent of cortical necrosis is largely confined to a narrow endosteal zone There are occasional areas of slightly deeper necrosis

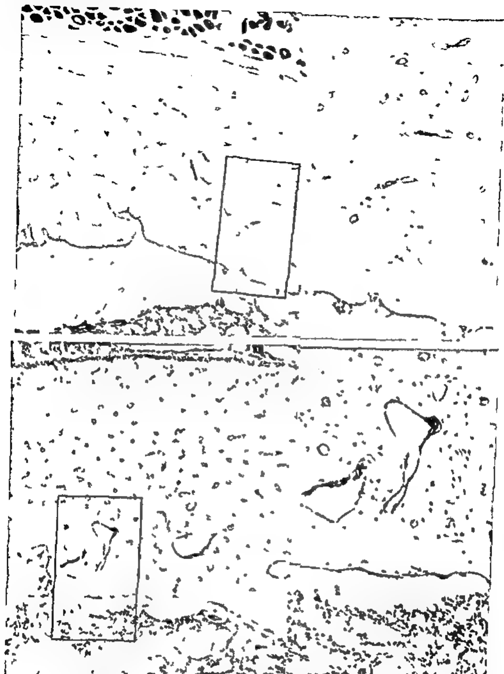

Fig 13 2 weeks, group 1 – R 6413 D (HE x 40, detail x 100) Hardly thickened periosteum, the new subperiosteal layer has been incorporated in the old cortex … There is a new endosteum … generation of bone marrow

Fig 14 2 weeks, group 2 – L 6600 D (HE x 40, detail x 100) The features resemble those of group 1 Resorption lacunae are observed in the inner side of the cortex

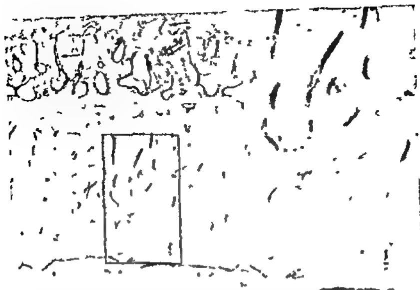

Fig 15 2 weeks group 3 – L 6453 D Su (HE x 40 detail x 85) Greatly thickened periosteum thick irregular layer of woven bone in which many Micropaque filled blood vessels (arrows) At least two-thirds of the cortex is necrotic, but islets with vital osteocytes remain No new endosteum is found (detail)

The endosteum shows resorption lacunae indicating removal of dead bone, new bone is being deposited around these areas A new endosteum is present, from which young lamellated bone is being formed The subperiosteal layer of woven bone shows a more mature appearance, and at most sites is incorporated in the old cortex (fig 13) A new endosteal vascularization has developed in the medullary cavity, where pluripotent mesenchymal cells differentiate to bone marrow elements, but can also form small bone speculae These are stained by the fluorochrome given last (Alizarin Red S)

The observations in *group* 2 are almost identical (fig 14) A connective tissue membrane has formed around the intramedullary rod

In *group 3*, as in groups 1 and 2, the extent of the cortical necrosis after 2 weeks is clearly visible At least two-thirds of the cortex is dead, and at some sites more In the necrotic cortex, however, islets of vital tissue have remained intact Resorption lacunae are occasionally visible at the boundary of the outer two-thirds and inner one third The endosteum has disappeared There is still a marked subperiosteal reaction, and the periosteum itself has greatly increased in thickness The medullary cavity is translucent (fig 15)

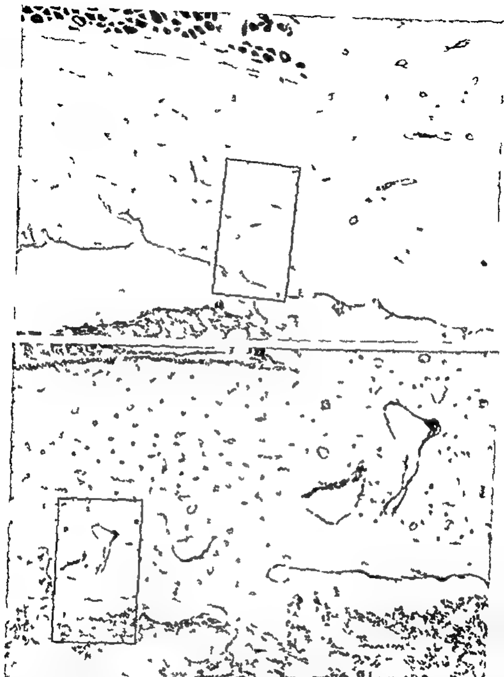

Fig 13 2 weeks group I – R 6413 ■ (HE x 40 detail x 100) Hardly thickened periosteum the new subperiosteal layer has been incorporated *in the old cortex* Cortical necrosis ■ confined to a narrow endosteal layer There is a new endosteum which is forming bone (detail) In the medullary cavity regenerat on *of bone marrow* elements and formation of bone spicules

Fig 14 2 weeks group 2 – L 6600 ■ (HE x 40 detail x 100) The features resemble those of group 1 Resorption lacunae are observed in the inner side of the cortex

Fig 17 2 weeks group 5 – L 6476 B (HE x 40 deta l x 120) Cort cal necros s sl ghtly more extens ve than that in groups 1 and 2 but features are nevertheless very s m lar Dead bone fragments and debr s are v s ble in the medullary cavity i e in the pores of the cement

Occasionally new medullary blood vessels can be seen pressed close aga nst the cortex

Observation period 3 weeks

In *group 1* the necrosis of the inner cortex is actively resorbed res orption lacunae increase in number and size and new cellular bone is deposited around them The new layer of endosteal bone which is depos ted in lamellae has slightly increased in thickness The vasculari zation in the periosteum has d minished to normal proportions Numerous new blood vessels are present in the medullary cavity

The sections in group 2 show identical features

In *group 3* too regeneration of the cortex has started to replace areas of necrosis Resorption lacunae are still being found in the outer cortex

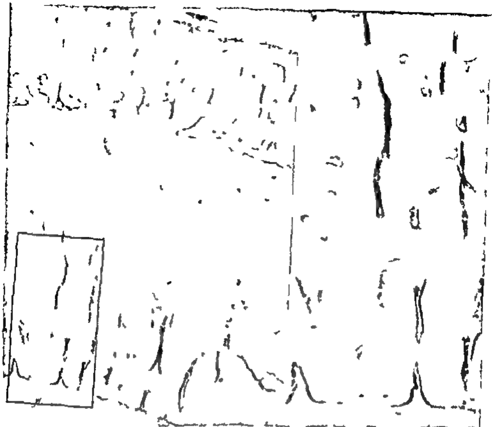

Fig 16 2 weeks group 4 – L 6405 II Su–C (HE x 32 detail x 110) Highly vas
cularized periosteum greatly increased in thickness at some sites external callus
has almost twice the thickness of the old cortex Deep necrosis of nearly the entire
cortex No islets with vital cells are observed (detail)

In *group 4* the cortical necrosis is most extensive Only an exceedingly narrow zone of cellular tissue has remained at the outer margin of the cortex On the outside there is a thick layer of new woven bone, which at some sites has the same diameter as the old cortex The necrosis is of much more „intensive" character because islets of vital tissue are not found anywhere in the dead cortex, as they were in group 3 (fig 16) Implantation of acrylic „cement" with an overdose of monomer proves to cause the most radical damage of cortical bone tissue

The sections in *group 5* are most reminiscent of those in groups 1 and 2 The necrosis is confined to the inner one-third of the cortex, but ample cellularized areas are found here At most sites new endosteum has been formed, which contributes to endosteal osteogenesis The thin layer of new subperiosteal bone is incorporated in the old cortex The medullary cavity contains dead bone fragments and debris (fig 17) This material must be localized in the pores of the modified acrylic cement

Fig 17 2 *weeks, group 5* – L 6476 B (HE x 40 detail x 120) Cortical necrosis slightly more extensive than that in groups 1 and 2 but features are nevertheless very similar Dead bone fragments and debris are visible in the medullary cavity, i e in the pores of the cement

Occasionally new medullary blood vessels can be seen pressed close against the cortex

Observation period 3 weeks

In *group 1* the necrosis of the inner cortex is actively resorbed, resorption lacunae increase in number and size, and new cellular bone is deposited around them The new layer of endosteal bone, which is deposited in lamellae, has slightly increased in thickness The vascularization in the periosteum has diminished to normal proportions Numerous new blood vessels are present in the medullary cavity

The sections in *group* 2 show identical features

In *group 3*, too, regeneration of the cortex has started to replace areas of necrosis Resorption lacunae are still being found in the outer cortex,

usually at the boundary between two thirds and one-third, but sometimes halfway *From the periosteum, tongues of cellular tissue invade the* necrotic cortex and seek communication with islets of still vital bone There is still a distinct line of demarcation between the subperiosteal bone layers and the old cortex At a few sites the endosteum is beginning to restore itself There is no connective tissue membrane between end osteum and acrylic cement

In *group 4* large resorption lacunae are beginning to form in the outer layers of the necrotic cortex The external callus is as thick as the old cortex, from which it is clearly demarcated

In *group 5* resorption lacunae are likewise visible, but at the boundary between one-third and two-thirds, viewed from the inside The cortical necrosis, which is slightly more extensive than that in groups 1 and 2, is being actively resorbed The endosteal bone layer has substantially increased in thickness Close against the cortex in the medullary cavity, many more new Micropaque-filled blood vessels are perceived than after 2 weeks' observation

Observation period 4 weeks

The sections in *group 1* show more advanced organization of the necrosis The resorption lacunae remain small and lie close against the regenerating endosteal lamellae At some sites, in fact, hardly any evidence of necrosis is left In the medullary cavity the bone marrow shows an increasingly normal appearance, but many islets of bone persist

In *group 2* the sections show no essential differences from those of group 1

In *group 3* the organization of the cortical necrosis advances Resorption lacunae are found in the inner cortical layers as well At most sites there is new endosteum which, however, does not yet contribute to osteogenesis The subperiosteal zone of new bone is maturing to lamellated bone and the demarcation from the old cortex is fading The medullary cavity remains translucent, specifically, no new vessels are seen and there is no connective tissue membrane between endosteal cortex and acrylic cement surface

In *group 4* elongated resorption lacunae are localized at the boundary between old and „new" cortex The latter has matured, lamellated bone having replaced *virtually all the woven bone In the* dead cortex, *occasi* onal vital osteocytes are only seen around resorption lacunae of ever increasing size There is as yet no endosteum and the medullary cavity remains translucent

The sections in *group 5* show very active regeneration of the necrotic cortex by formation of resorption lacunae in the inner cortex and by „creeping substitution" from the inner and middle cortical layers The layer of new endosteal bone increases in thickness, and the number of

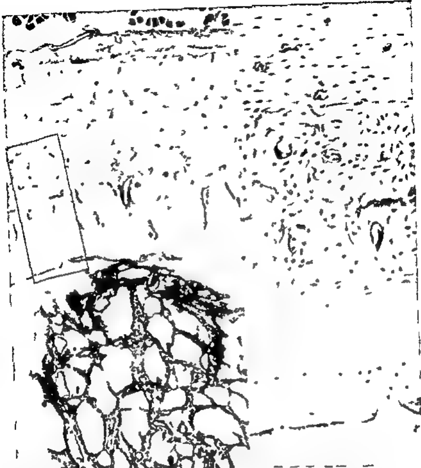

Fig 18 6 weeks group 1 – R 6424 C (HE x 40 detail x 128) On the endosteal side of the cortex there is still a narrow zone of dead bone demarcated from the medullary cavity by a new layer of lamellated bone In the medullary cavity young bone tissue is visible there deposited next to bone marrow elements during regeneration

blood vessels in the medullary cavity also shows some increase An occasional vessel is observed in the centre of the medullary cavity, but most vessels are still localized close to the endosteum Particles of contrast medium (zirconium dioxide) are observed in the medullary cavity

Observation period 5 weeks

The above mentioned processes are advancing in each of the 5 groups

In *groups 1 and 2* the amount of bone localized in the medullary cavity increases

usually at the boundary between two-thirds and one-third, but sometimes halfway From the periosteum, tongues of cellular tissue invade the necrotic cortex and seek communication with islets of still vital bone There is still a distinct line of demarcation between the subperiosteal bone layers and the old cortex At a few sites the endosteum is beginning to restore itself There is no connective tissue membrane between endosteum and acrylic cement

In *group 4* large resorption lacunae are beginning to form in the outer layers of the necrotic cortex The external callus is as thick as the old cortex, from which it is clearly demarcated

In *group 5* resorption lacunae are likewise visible, but at the boundary between one-third and two-thirds, viewed from the inside The cortical necrosis, which is slightly more extensive than that in groups 1 and 2, is being actively resorbed The endosteal bone layer has substantially increased in thickness Close against the cortex in the medullary cavity, many more new Micropaque-filled blood vessels are perceived than after 2 weeks' observation

Observation period 4 weeks

The sections in *group 1* show more advanced organization of the necrosis The resorption lacunae remain small and lie close against the regenerating endosteal lamellae At some sites, in fact, hardly any evidence of necrosis is left In the medullary cavity the bone marrow shows an increasingly normal appearance, but many islets of bone persist

In *group 2* the sections show no essential differences from those of group 1

In *group 3* the organization of the cortical necrosis advances Resorption lacunae are found in the inner cortical layers as well At most sites there is new endosteum which, however, does not yet contribute to osteogenesis The subperiosteal zone of new bone is maturing to lamellated bone and the demarcation from the old cortex is fading The medullary cavity remains translucent, specifically, no new vessels are seen and there is no connective tissue membrane between endosteal cortex and acrylic cement surface

In *group 4* elongated resorption lacunae are localized at the boundary between old and „new' cortex The latter has matured, lamellated bone having replaced virtually all the woven bone In the dead cortex, occasional vital osteocytes are only seen around resorption lacunae of ever increasing size There is as yet no endosteum and the medullary cavity remains translucent

The sections in *group 5* show very active regeneration of the necrotic cortex by formation of resorption lacunae in the inner cortex and by „creeping substitution" from the inner and middle cortical layers The layer of new endosteal bone increases in thickness, and the number of

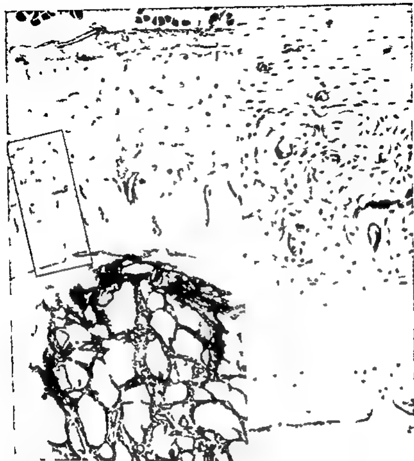

Fig 18 6 side of the c medullary ca bone tissue ... deposited next to bone marrow elements during regeneration

blood vessels in the medullary cavity also shows some increase An occasional vessel is observed in the centre of the medullary cavity, but most vessels are still localized close to the endosteum Particles of contrast medium (zirconium dioxide) are observed in the medullary cavity

Observation period 5 weeks

The above mentioned processes are advancing in each of the 5 groups

In *groups 1 and 2* the amount of bone localized in the medullary cavity increases

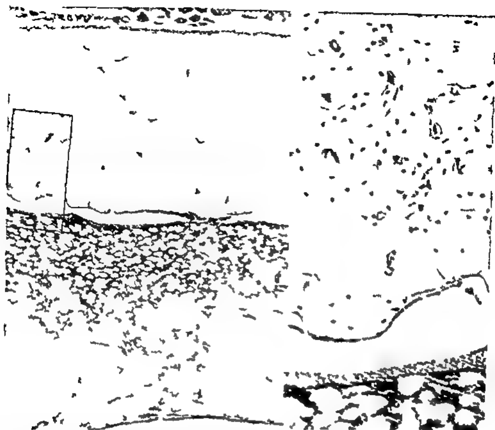

Fig 19 6 weeks group 2 L 6541 B (HE x 35 detail x 128) Nearly normal features of cortex except for a narrow necrotic zone Normal bone marrow The Palacos rod (dissolved) is surrounded by a narrow connective tissue membrane A Micropaque filled blood vessel is visible in the periosteum

In *group 3* the regenerated endosteum begins to form a thin layer of lamellated bone At occasional sites fragments of the necrotic cortex are cast off into the medullary cavity as sequestra and replaced by vital bone marrow

In *group 4* too there is sequestration of necrotic endosteal cortex to the medullary cavity New endosteum is still largely unformed The necrosis has so weakened the bone that it readily ruptures when sections are being cut The subperiosteal layer of new bone is not incorporated in the cortex

In *group 5* the most striking feature is the increase in the number of medullary vessels which are now localized also in the centre of the medullary structures must be localized in pores of the modified acrylic cement) In a number of specimens (rabbit 6497 [illegible] and D) even intra medullary bone is observed

Fig 20 6 weeks group 3 – L 6424 C - Pa (HE x 35, detail x 105) Still necrosis of one half to two thirds of the cortex, but active regeneration is in progress Tongues of vital tissue grow into the necrotic cortex from the outside New bone is being deposited around resorption lacunae There is modest endosteal bone apposition The subperiosteal bone layer has matured but is still distinguishable from the old cortex

Observation period 6 weeks

In *group 1*, all that remains of the necrotic cortex is a narrow zone on the inside, which is demarcated from the medullary cavity by a layer of newly formed bone At some sites a large amount of bone is still seen in the medullary cavity, which shows abundant vascularization (fig 18)

The sections in *group 2* show identical features, the bone marrow presenting quite a normal appearance (fig 19)

In *group 3* half the cortex still shows necrosis, and active regeneration of new bone takes place Otherwise there are few changes (fig 20)

Group 4 shows but little progress in the restoration of the extensive necrosis No new endosteal bone has yet been formed (fig 21)

Group 5 again shows a close resemblance to groups 1 and 2 The necrotic layer on the inside of the cortex is slightly wider, however (fig 22) A very interesting observation is made in the sections from both animals in group 5 New bone is localized in the centre of the medullary cavity (fig 23)' It is well vascularized, as is demonstrated by many small Micropaque-filled vessels found in and around this bone At some sites

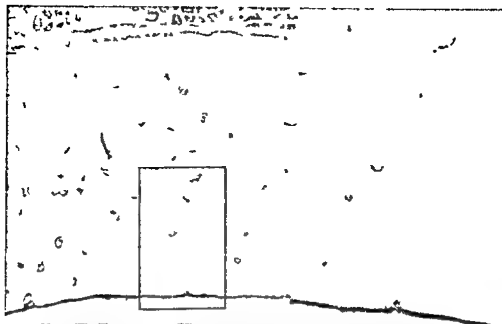

Fig 21 6 weeks group 4 – L 750 D Pa–C (HE x 40 detail x 100) By far the most severe necrosis Islets of new bone are being formed from the subperiosteal layer There is hardly any endosteal regeneration and no endosteal bone apposition is observed

it is localized against small dead bone fragments The new intramedullary bone is often localized in streaks of vital bone marrow All these intra medullary structures must be localized in pores of the modified acrylic cement This, however, has dissolved due to the processing of the material But there remain particles of contrast medium which are trapped in the intramedullary structures (fig 23) These particles are birefringent in polarized light They are only very rarely seen in groups 2, 3 and 4, where the cement is solid

Observation period 7 weeks

In *group 1* an occasional endosteal necrotic area is still seen, but the cortex has been restored for the greater part The above described new bone in the medullary cavity has disappeared to be replaced by normal bone marrow elements which are more abundantly vascularized than in the control sections

The sections in *group 2* show the same features as those in group 1

Group 3 shows evidence of further organization and resorption of the necrosis The resorption lacunae become slightly larger and some bone marrow sometimes appears in them In some cases a very thin layer of connective tissue is seen along the new endosteum

In *group 4*, new endosteum is seen in only an occasional specimen, it is usually still absent The features of a deep inert necrosis of nearly

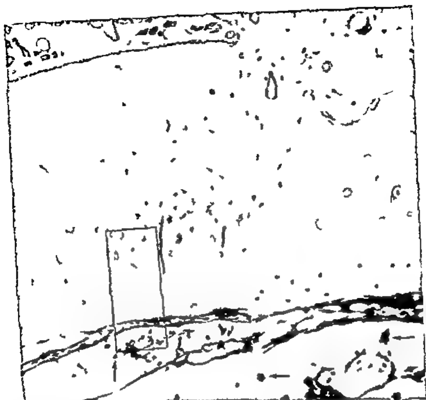

Fig 22 6 weeks group 5 – L 6490 B (HE x 40 detail x 128) Features resemble those shown in figures 18 and 19 but the necrotic zone is slightly thicker Pronounced layer of endosteal bone apposition Strands of bone marrow and young bone in the medullary cavity As remnants of the dissolved acrylic cement, contrast medium particles have remained intact (arrows)

the entire old cortex continue to dominate Only the resorption lacunae increase in size and are now seen also on the inside of the cortex Some are filled with bone marrow On the inside of the cortex dead bone slivers are occasionally cast off into the medullary cavity

In *group 5* the necrosis also shows a considerable degree of organization but less advanced than that in groups 1 and 2 Bone and bone marrow grow into the cement pores resembling the changes occurring after 6 weeks This is observed in both animals and in all sections of segments A through D

Observation period 3 months

In *group 1* all sections from both animals show largely normal features

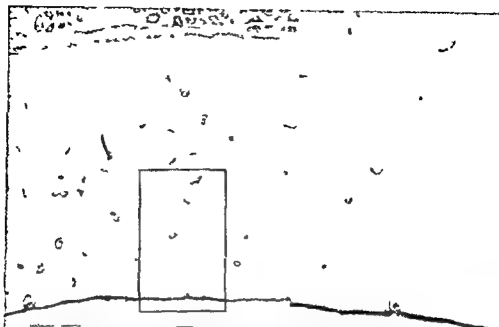

Fig 21 6 weeks group 4 – L 750 D Pa–C (HE x 40 detail x 100) By far the most severe necrosis Islets of new bone are being formed from the subperiosteal layer There is hardly any endosteal regeneration and no endosteal bone apposition is observed

it is localized against small dead bone fragments The new intramedullary bone is often localized in streaks of vital bone marrow All these intra medullary structures must be localized in pores of the modified acrylic cement This however, has dissolved due to the processing of the material But there remain particles of contrast medium which are trapped in the intramedullary structures (fig 23) These particles are birefringent in polarized light They are only very rarely seen in groups 2 3 and 4 where the cement is solid

Observation period 7 weeks

In *group 1* an occasional endosteal necrotic area is still seen but the cortex has been restored for the greater part The above described new bone in the medullary cavity has disappeared to be replaced by normal bone marrow elements which are more abundantly vascularized than in the control sections

The sections in *group 2* show the same features as those in group 1

Group 3 shows evidence of further organization and resorption of the necrosis The resorption lacunae become slightly larger and some bone marrow sometimes appears in them In some cases a very thin layer of connective tissue is seen along the new endosteum

In *group 4*, new endosteum is seen in only an occasional specimen it is usually still absent The features of a deep inert necrosis of nearly

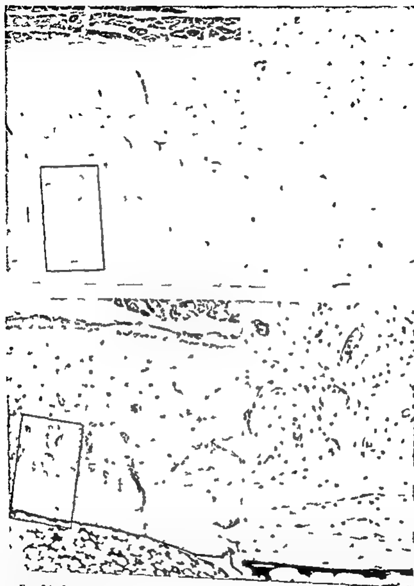

Fig 24 3 months group 1 – L 6467 II (HE x 40 detail x 110) Virtually normal features of the cortex

Fig 25 3 months group 2 – L 6539 D (HE x 40 detail x 117) Normal features of the cortex

Fig 23 [illegible] *weeks group 5* – L 6490 B (HE x 25 (A) detail x 110 (B) detail x 110 (C)) Strands of regenerated bone marrow and bone islets in the pores of the modified acrylic cement Very active medullary revascularization (fig 23A fig 23C) New bone (fig 23B) can be deposited near dead bone fragments detached during reaming (arrow 1) Contrast medium particles are caught by the new intra medullary structures (arrow 2) The bone tissue in the pores is well vascularized by Micropaque filled vessels (arrow 3) Detail of the Micropaque filled artery and arterioles localized next to a bone spicule (fig 23C)

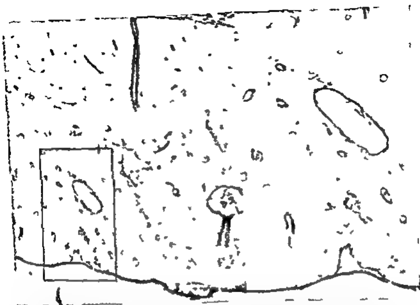

Fig 27 3 months group 4 – L 6561 B - Pa–C (HE x 40, detail x 92) Very extensive cortical necrosis Resorption lacunae throughout the cortex serve as centres for islets of vital bone tissue The endosteum has regenerated and a thin zone of bone is being endosteally deposited

In *group 5* the cortical necrosis in the inner zone is less organized than in groups 1 and 2 but nevertheless is pushed further and further back Due to increasing regeneration the bone gives an impression of vitality Resorption lacunae of the size seen in group 3 and 4 are entirely absent (fig 28)

The growth of bone into the cement pores has evidently increased since the observations of 6 to 7 weeks The medullary cavity is traversed by whole bone bridges with ramifications in all directions (fig 29) This is not an incidental finding but a constant feature in all sections of the treated femurs of both animals The granules of contrast medium are seen as small black dots among the bone and bone marrow spikes They are apparently retained by the in-grown tissue, while the acrylic cement itself dissolves as a result of the processing of the sections (fig 30A) In polarized light these crystals are birefringent (fig 30B)

Observation period 6 months

In *groups 1 and 2*, cortical bone and bone marrow have completely recovered from the operative trauma and present a normal appearance

In *groups 3 and 4*, the „cancellization" or „medullization" of the cortex has continued Large resorption lacunae filled with bone marrow

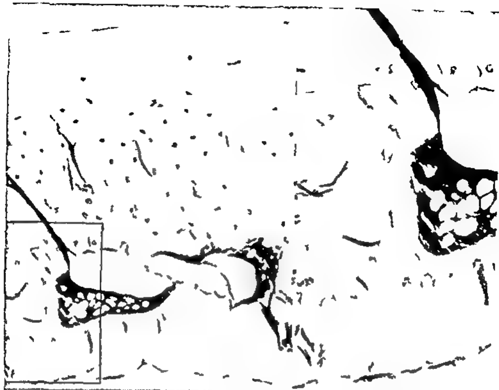

Fig 26 3 months group 3 – L 6441 D Pa (HE x 40 detail x 90) Necros s of *the inner half of the cortex is still predominant Large resorption lacunae often* filled with bone marrow in necrotic areas of the inner cortical layers Vital bone is be ng deposited around these lacunae Intact endosteum and endosteal bone ap position increased in thickness

Very occasionally a small focus of necrosis is still observed in the inner part of the cortex (fig 24)

The same applies to *group 2* (fig 25) The connective tissue membrane around *the Palacos rod has increased in thickness*

In *group 3* the resorption lacunae prove to have considerably increased *in size The majority contain normal bone marrow and are localized on* the inside of the cortex They are demarcated from the medullary cavity by a thicker layer of lamellated endosteal bone The endosteum is intact The medullary cavity is translucent (fig 26)

In *group 4* the extent of cortical necrosis is still impressive Resorption lacunae are seen throughout the cortex a few of them contain bone marrow Most of these lacunae are the centre of islets of highly cellular bone tissue The subperiosteally appositioned bone has matured and been incorporated in the cortex The endosteum has recovered and deposits a thin layer of endosteal bone *The medullary cavity remains translucent* (fig 27)

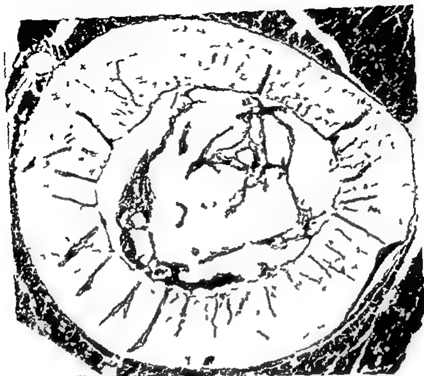

Fig 29 3 months group 5 L 6487 B (HE × 11) *General view to demonstrate the intramedullary distribution of the bone and bone marrow tissue grown into the cement pores Fig 28 shows a detail of this section*

As compared with the features observed after 3 months the intra medullary growth of bone and bone marrow into pores of the modified acrylic cement has increased This is a constant feature in all sections from both animals (fig. 35A fig 35B)

Observation period 9 12 and 24 months

Only 6 animals of *group 3* (implantation of commercial acrylic cement) were followed up over a longer period of time (table 2)

After 9 *months* there is a predominance of the previously described features of large resorption lacunae filled with bone marrow (medullization of the cortex) and sequestration of dead bone into the medullary cavity Resorbed and sequestrated dead bone is replaced by bone marrow Large necrotic areas are still seen in the inner half of the cortex An unmistakable connective tissue membrane is seen in the interface between acrylic cement and bone

Fig 28 3 months group 5 – L 6482 II (HE x 40 detail x 128) The necrosis in the inner cortical layer is being further resorbed and superseded The cortex gives an impression of vitality Growth of bone and bone marrow into the pores of the modified acrylic cement Large resorption lacunae are not observed anywhere This photomicrograph is a detail from fig 29

are localized in the necrotic inner half of the cortex (fig 31, fig 32) At some sites fragments of dead cortical bone are sequestrated into the medullary cavity (fig 34) This is particularly evident in group 4 A thin connective tissue membrane is occasionally encountered in the interface between bone and acrylic cement It can contain giant cells

In *group 5* the necrosis of the inner cortex has practically disappeared (fig 33) although an evidently poorly cellularized area is occasionally still seen There are no large resorption lacunae as observed in groups 3 and 4 The new endosteal bone layer has for the greater part increased in thickness

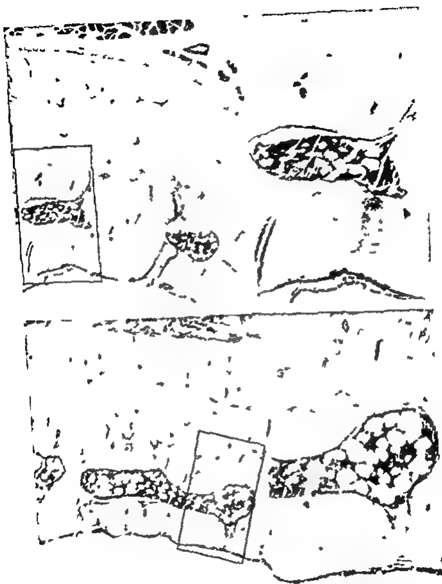

Fig 31 6 mo ul s group 3 – L 741 D Su (HE x 40 detail x 90) Medull zation of the necrot c cortex Large resorpt on lacunae f lled with bone marrow in the *nner half of the cortex*

Fig 32 6 months group 4 – L 6504 B Pa–C (HE x 40 deta l x 90) Medul l zat on in a cortex recover ng from very extensive necros s

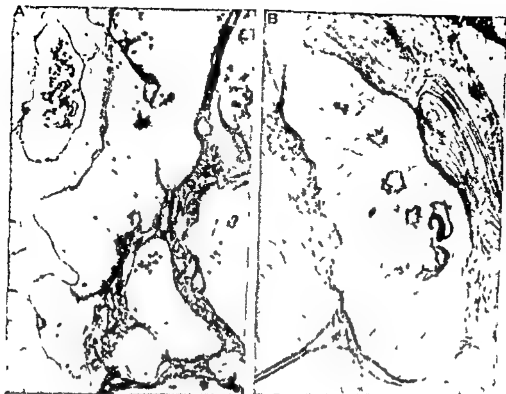

Fig 30 3 months, group 5 – L 6485 D (HE x 37, detail x 90) Granules of contrast medium (black dots) are enclosed by the bone grown into the pores of the cement The development of this bony bridge could be exactly followed by a study of consecutive sections (fig 30A) In polarized light the birefringent crystals of contrast medium stand out white The bone trabeculae growing together show the structure of young bone (fig 30B)

After *12 months* there are no essential further changes (fig 36)

After *24 months* all dead tissue has been replaced by vital bone or resorbed The acrylic cement is bounded by a thick connective tissue membrane which can contain giant cells The entire necrotic inner half of the cortex has been replaced by bone marrow In the remaining cortex, which consists of the old outer half of the cortex and the newly formed subperiosteal bone, dead tissue is no longer encountered (fig 37)

4.5. *Angiographic findings*

Although the Micropaque perfusion technique used was not always found to be optimal, the results obtained were of value as a supplement to the histological findings

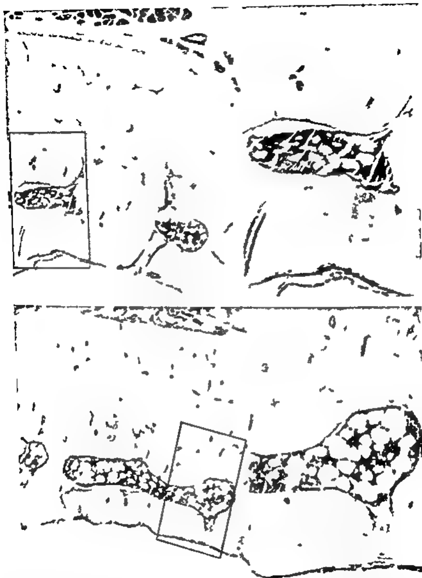

Fig 31 6 n o ths group 3 — L 741 III Su (HE x 40 deta l x 90) Medullizat on of the necrot c cortex Large resorpt on lacunae f lled with bone marrow in the nner half of the cortex

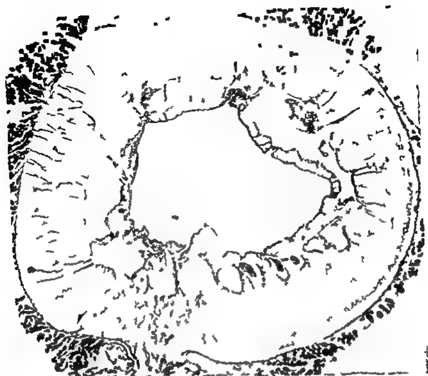
Fig 32 6 months group 4 L 6504 B Pa—C (HE x 40 detail x 90) Medul l zat on in a cortex recover ng from very extensive necros s

Fig 33 6 months group 5 – L 6486 B (HE x 40 detail x 145) Virtually complete resorption of the necrosis of the inner cortex Resorption lacunae of the size observed in groups 3 and 4 are not found anywhere

4 5 1 *Macro-angiography*

In the untreated femur used as control, the entry of the nutrient artery was constantly found at the same site, immediately distal to the lesser trochanter on the medioposterior aspect of the femoral shaft (fig 2A,B) The bifurcation into ascending and descending branches immediately after the passage through the nutrient foramen was likewise a constant finding However, the number and calibre of these branches varied

Evaluation of the macroscopic vascularization of the treated femur was impeded by the presence of the extra osseous vessels in the muscular coat around the bone, by the radiopaque contrast medium in the acrylic cement, and by the density of the cortex as such



Observation period 1 week

In none of the 5 groups is a nutrient artery visible (fig 38A, fig 38B)

Observation period 2 7 weeks

In *group 1* the typical course of the nutrient artery reappears after 2 weeks and *shows nearly complete recovery after 5 weeks*

In *group 2* the course of the nutrient artery is of course influenced by

F g 34 6 mon l s group 3 L 741 C Su (HE x 11) General v ew of cancel l zat on or „medull zat on of the cortex Sequestrat on of dead bone into the medullary cav y Th n connect ve t ssue membrane n the bone/cement interface The medullary cav ty s translucent

the intramedullary rod but vessels are clearly seen to extend along the rod after 5 weeks (fig 38C)

In *groups 3 4 and 5* as expected the obliterated nutrient artery is nowhere to be seen after fill ng of the medullary cavity with acrylic cement

Observation period 3 and 6 months

In *group 1* the nutrient artery has returned to normal after 3 months

In *group 2* the ascending and descending branches of the nutrient artery which extend along the rod can be clearly differentiated after 3 months

In *groups 3 and 4* there is nothing to suggest regeneration of arterial branches after 6 months

In *group 5* an occas onal Microtrast filled vessel appears in the cement

Fig 33 6 months group 5 – L 6486 B (HE x 40, detail x 145) Virtually complete resorption of the necrosis of the inner cortex Resorption lacunae of the size observed in groups 3 and 4 are not found anywhere

4 5 1 Macro angiography

In the untreated femur used as control, the entry of the nutrient artery was constantly found at the same site, immediately distal to the lesser trochanter on the medioposterior aspect of the femoral shaft (fig 2A,B) The bifurcation into ascending and descending branches immediately after the passage through the nutrient foramen was likewise a constant finding However, the number and calibre of these branches varied

Evaluation of the macroscopic vascularization of the treated femur was impeded by the presence of the extra osseous vessels in the muscular coat around the bone, by the radiopaque contrast medium in the acrylic cement, and by the density of the cortex as such

Observation period 1 week

In none of the 5 groups is a nutrient artery visible (fig 38A, fig 38B)

Observation period 2-7 weeks

In *group 1* the typical course of the nutrient artery reappears after 2 weeks and shows nearly complete recovery after 5 weeks

In *group 2* the course of the nutrient artery is of course influenced by

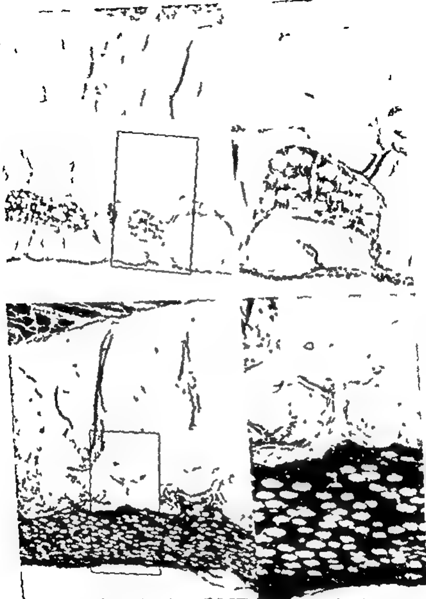


Fig 36 12 ı onths group 3 – L 328 ■ Pa (HE x 40 detail *x 92)* Large resorption lacunae f lled with bone marrow are seen in the ···· the cortex Necrotic bone ··· The remain ng cortex still to the subperiosteally appc

Fig 37 24 months group 3 – L 358 B Pa (HE x 40 detail *x 100)* The necrotic nner half of the cortex has been replaced by bone marrow and is separated from the acryl c cement by a th ck connective tissue membrane The remainder of the old cortex is v tal but shows a somewhat erratic architecture

Fig 35 6 months group 5 — L 6487 II (HE x 11 detail x 45) General view of the growth of tissue into the pores of the modified cement Bone processes traverse the medullary cavity (fig 35A) and can attain a considerable thickness (fig 35B) As remnants of the acrylic cement dissolved in processing occasional granules of contrast medium are encountered

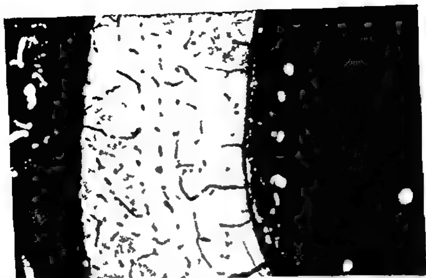

Fig 39 The normal micro-angiogram of the control femur R 6445 D (x 40) It is to be borne in mind that stimulated vascularization (Rhinelander 1972) may still be involved because the left femur of the same animal was operated on 6 weeks earlier (table 2 group 4b)

after 3 months but this can be followed only over a distance of a few millimetres After 6 months the features are more sharply defined However, the possibility that extraosseous vessels extending in the muscular coat are involved cannot be excluded with certainty

Observation period 9 24 months

In *group 3*, blood vessels extending longitudinally between acrylic cement and cortex can be observed from the 9th month on

4 5 2 Micro angiography

The *normal* micro-angiographic features of the control femur show the Micropaque filled medullary arteries while in the intracortical canals only an occasional small vessel fills with contrast medium Extraosseous vessels around the cortex are likewise filled (fig 39)

Observation period 1 week

As the histological material also showed, numerous new blood vessels are already present in the medullary cavity in *group 1* Vessels are seen also in the cortex but in particular the subperiosteal zone of new bone is richly vascularized by blood vessels extending perpendicular to the cortex This pattern of vascularization is also observed in *group 2*

Fig 38 Anteroposterior radiographs of rabbits femurs using the mammography technique In group 1 (R 6420) the nutrient artery [illegible] interrupted one week after reaming and suction of the medullary cavity There are occasional signs of regeneration (A) In group 5 (L 6475) there is no longer any visible trace of the nutrient artery The medullary cavity is filled with modified acrylic cement (B) In group [illegible] (L 6597), slender longitudinal vessels are seen to extend along the Palacos rod 5 weeks after reaming and suction of the medullary cavity and introduction of an intramedullary acrylic cement rod (C)

In *group 3*, no vessels are visible in medullary cavity and old cortex, only a thick subperiosteal layer of new bone is richly vascularized by extraosseous vessels which have substantially increased in calibre and number The same features are seen in *group 4*, in which in particular the thickness of the layer of appositional bone is striking

The micro angiograms of *group 5* show a striking resemblance to those of groups 1 and 2, but no vessels are visible in the medullary cavity

Observation period 2-7 weeks

From the 2nd week on the medullary revascularization in *groups 1 and 2* increases enormously, these vessels being many times as large in number and calibre as those in the control femur The medullary cavity contains bone spicules deposited there during regeneration of medullary contents In the cortex the endosteal vascularization increases, the entire cortex being revascularized after 3 weeks With the increase in medullary vessels vascular overfilling in the new subperiosteal bone ceases, and returns to normal proportions in the 3rd week (fig 40, fig 41)

In *groups 3 and 4* medullary revascularization takes a much slower course Up to the 6th week, no new medullary vessels are observed, and it is not until after 5 6 weeks that reactive vascularization in the woven subperiosteal bone has normalized Only after 4 weeks in *group 3* and after 6 weeks in *group 4* are sufficient endosteal vessels in the cortex observed to warrant the conclusion of a restored cortical vascularization The impression is that cortical revascularization takes place *from periosteum to endosteum* in these two groups (fig 42, fig 43) After 6 weeks Micropaque filled vessels are seen between cortex and acrylic cement in both groups (fig 45)

Just as with the histological material, the micro angiograms of *group 5* are most reminiscent of those in groups 1 and 2 From the *2nd week on*, new blood vessels are observed in the medullary cavity, and Micropaque-filled vessels are seen endosteally at most sites in the cortex Cortical vascularization has been restored after *3 weeks (fig 44)* Medullary vessels gradually increase in number, and after 6 weeks there is enormous proliferation of these new vessels and vascularized bone spicules, which must be localized in the *pores of the* cement, are observed (fig 46)

Observation period 3 and 6 months

At 3 months, cortical vascularization in all groups has returned to normal in the sense that *the* pattern of vascularization resembles *that* shown in fig 39

In *group 1* the vascularization of the medullary cavity has also normalized after 3 months *The same applies* to group 2, although here space is occupied by the rod, surrounded by a vascularized *connective* tissue membrane.

Fig 40 3 weeks group 1 – R 6411 D (micro angiogram x 40) Normalization of the pattern of vascularization of the cortex Still unmistakable activity of extra osseous vessels New blood vessels and bone spicules in the medullary cavity

Fig 41 3 weeks group 2 – L 6545 D (micro angiogram x 40) Virtually normal cortical vascularization The zone of subperiosteally apposed bone is clearly identifiable Very active regeneration of the medullary vessels with numerous bone spicules

Fig 44 3 weeks group 5 – L 6493 ■ (micro angiogram x 40) Active and completed revascularization of the cortex but as yet no normal features The subperiosteal layer of new bone comprises a few small vessels perpendicular to the cortex The medullary cavity contains new medullary blood vessels which are distinguishable from the radiopaque material of the modified acrylic cement

In *groups 3 and 4* vessels are seen between acrylic cement and bone along the endosteal margin of the cortex They have increased in number and size and sometimes form small „lakes' Otherwise the medullary cavity remains translucent

In *group 5* the medullary vascularization increases further after 3 and after 6 months, and the same applies to the amount of bone tissue localized in the pores of the cement (fig 47) After 6 months the intramedullary bone has matured further and is therefore better visible radiologically

Observation period 9, 12 and 24 months

In *group 3* the pattern of medullary vascularization shows no further essential changes

4 6 *The normal fluorescence microscopic features on the control side*

Knowledge of the normal process of growth remodelling of the metaphyses and diaphyses of long bones is essential in the understanding and

Fig 42 3 weeks group 3 – L 6410 C Pa (m cro angiogram x 40) Many M cro paque filled blood vessels are vis ble particularly in the subperiosteal layer of new bone Only an occasional vessel has filled in the endosteal part of the cortex No blood vessels in the medullary cavity

Fig 43 3 weeks group 4 L 6414 ◻ Su–C (micro angiogram x 40) Marked vascular activ ty in the subperiosteal bone layer the impression is that the cortex is being revascularized from this layer As yet no M cropaque filled vessels in the inner part of cortex The medullary cavity is translucent

Fig 44 3 weeks group 5 – L 6493 D (micro angiogram x 40) Active and completed revascularization of the cortex, but as yet no normal features The subperiosteal layer of new bone comprises a few small vessels perpendicular to the cortex The medullary cavity contains new medullary blood vessels which are distinguishable from the radiopaque material of the modified acrylic cement

In *groups 3 and 4* vessels are seen between acrylic cement and bone along the endosteal margin of the cortex They have increased in number and size and sometimes form small „lakes' Otherwise the medullary cavity remains translucent

In *group 5* the medullary vascularization increases further after 3 and after 6 months, and the same applies to the amount of bone tissue localized in the pores of the cement (fig 47) After 6 months the intramedullary bone has matured further and is therefore better visible radiologically

Observation period ▪ 12 and 24 months

In *group 3* the pattern of medullary vascularization shows no further essential changes

completion of the picture obtained after studying the histological material Since the changes on the endosteal side of the cortex were particularly important for this study, the expected differences between the 5 groups could be most clearly demonstrated in the distal, partly metaphyseal sections D

Groups 1 and 2 show unmistakable restoration of the expected growth pattern in the diaphyseal as well as in the distal metaphyseal sections (fig 49B) As compared with the control sections there is somewhat more bone remodelling, particularly in the inner cortical layers

In *group 3* a very thin layer of bone proves to have been endosteally deposited at most sites The inner half of the cortex shows hardly any osteogenesis, whereas the outer half is characterized by great activity The new subperiosteal bone layer deposited during the first two post operative weeks, is clearly demarcated from the old cortex (fig 49C) A striking fact is that active remodelling processes are in progress throughout the diaphyseal as wel as the metaphyseal cortex in the region of the linea aspera (fig 49F, G)

In *group 4* no endosteal bone apposition is observed either in the diaphyseal or in the metaphyseal sections The subperiosteally deposited new bone layer attains a considerable thickness Here, too, the bone remodelling processes in the region of the linea aspera are further advanced than anywhere else in the cortex, where activity can be observed only in the outer zone (fig 49D)

In all sections of *group 5* intramedullary bone – coloured red by Alizarin complexon – is found Occasionally a green line (calcein green) is also observed Endosteal bone apposition is demonstrable throughout the distal metaphyseal and the diaphyseal sections Metaphyseally this bone is marked by several coloured lines (fig 49E) Remodelling pro cesses are in progress especially in the inner half of the cortex New osteons are coloured by several fluorochromes

4 8 *Macro-autoradiographic findings*

The *autoradiographic* control sections clearly demonstrated the growth remodelling of the longitudinally growing rabbit femur schematically shown in fig 48 (figs *50 51, 52*) The femurs were always paired for cutting so that on the film the treated femur could be compared with its control

Observation period 1 week

The autoradiograms of *groups 1 and 2* are identical Both show in creased periosteal activity, and an occasional dark line can also be observed in the metaphyseal endosteum (fig 50)

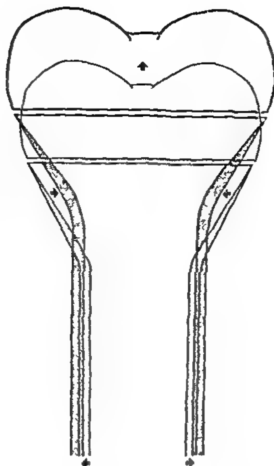

Fig 48 Schematic representation of some aspects of growth remodelling of long bones Arrows indicate the direction of growth

ated in the form of the thinner diaphysis The diaphysis assumes its definite typical size and dimensions during growth Due to torsion and development of cristae, this apposition usually does not have the same width all around its diameter In the metaphysis, too, the decrease in width is usually not circular due to the development of tuberosities, tubercles, ridges and grooves (Enlow 1968)

The above described growth remodelling patterns were also clearly demonstrated in the control femurs of the nearly 6-month-old rabbits by sequential labelling (fig 49A)

4 7 *Fluorescence-microscopic findings after 7 weeks*

As has already been pointed out, in particular the animals observed by sequential fluorochrome labelling during 7 weeks contributed to the

completion of the picture obtained after studying the histological material Since the changes on the endosteal side of the cortex were particularly important for this study the expected differences between the 5 groups could be most clearly demonstrated in the distal partly metaphyseal sections D

Groups 1 and 2 show unmistakable restoration of the expected growth pattern in the diaphyseal as well as in the distal metaphyseal sections (fig 49B) As compared with the control sections there is somewhat more bone remodelling, particularly in the inner cortical layers

In *group 3* a very thin layer of bone proves to have been endosteally deposited in most sites The inner half of the cortex shows hardly any osteogenesis, whereas the outer half is characterized by great [illegible] The new subperiosteal bone layer deposited during the first [illegible] operative weeks is clearly demarcated from the old cortex [illegible] A striking fact is that active remodelling processes are [illegible] throughout the diaphyseal as wel as the metaphyseal cortex [illegible] of the linea aspera (fig 49F, G)

Fig 49D 7 weeks, group 4 – L 6447 D - Su – C (III RS position 3, x 36) No endosteal bone apposition The subperiosteally apposed bone layer has the same thickness as the old cortex Cortical bone remodelling is more advanced in the region of the linea aspera than elsewhere in the cortex

Fig 49E 7 weeks, group 5 – L 6483 [redacted] (III RS position 3, x 36) Newly formed bone spicules [illegible] features of active remodelling A thin layer of subperiosteal bone formed during the first postoperative week has been labelled by xylenol orange and Alizarin complexon

Fig 49F 7 weeks, group 3 – L 6443 D Pa (III RS position 3, x 11) Active remodelling is observed at the level of the linea aspera but much less [redacted] other parts of the cortex *Fig 49G* (x 17), enlargement from fig 49F, to demonstrate the increased remodelling activity in detail

Groups 3 and 4 do not differ either There is greatly increased periosteal activity, and no labelling can be seen in the endosteum Both animals don't even show any activity in the distal femoral epiphysis (*fig 51*)

After introduction of modified acrylic cement (*group 5*), increased periosteal activity [redacted] likewise seen, while the endosteal bone has incorporated Strontium only at occasional sites in the metaphysis The features resemble those observed in groups 1 and 2

Observation period 4 weeks

As compared with their controls, the femur[redacted] in *groups 1 and 2* still show slightly increased periosteal activity, endosteal activity has increased [redacted] compared with that in the controls

Fig 50 1 week group 1 – 6463 (autoradiogram x 1) As compared with the control femur (left) periosteal activity has increased Endosteal activity in the metaphysis has diminished

Fig 51 1 week group 4 – 6458 (autoradiogram x 1) Greatly increased activity on the bone surface (left) no endosteal labelling at all The growth plate in the distal femur is empty ! The right femur used as control

In *group 3* the activity on the femoral surface is still slightly increased Endosteal radioactive labelling is much weaker than that in the control bone, and is interrupted in several places In *group 4* the femur shows as yet no endosteal activity at all The distal femoral epiphysis is labelled in group 3 as well as in group 4

In *group 5* the activity on the bone surface has virtually returned to normal, but endosteal labelling is weak and interrupted in several places

Observation period 4 months

The increased periosteal activity has returned to normal in *group 4* Restored endosteal labelling is observed although it is still interrupted at a few sites No , blacking has occurred in the medullary cavity

As compared with the control bone the treated femurs in *group 5*

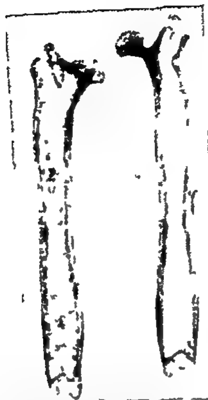

Fig 52 4 months group 5 – 6563 (autoradiogram x 1) Normalized periosteal activity slightly increased endosteal labelling Unlike the medullary cavity of the control femur (right) which shows no „blacking the bone grown into the cement pores has been labelled with Strontium[85]

show normalized periosteal but increased endosteal activity In the medullary cavity filled with modified acrylic cement the bone grown into the pores is labelled with Strontium[85] (fig 52)

4 9 *Discussion*

4 9 1 Discussion of results

The severity of the trauma inflicted could be deduced from the histological changes observed in medullary cavity cortex and periosteum after disturbance of the medullary vascularization and subsequent introduction of acrylic cement. Although in this experiment there seemed to be an evident correlation between the amounts of newly formed subperiosteal

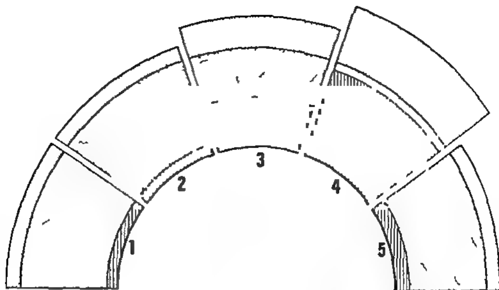

Fig 53 Schematic representation of the extent of the cortical necrosis (shaded area) and the reactive development of subperiosteal new bone (dotted area) in the 5 groups 2 weeks after operation

bone and the extent of the cortical necrosis yet the cortical necrosis was the principal yardstick used in evaluation of results The periosteum of immature rabbits (used in this study fig 7) is known to be more richly vascularized than that in adult animals After reaming of the medullary cavity of the rabbit tibia Danckwardt Lillieström (1969) found that growing animals were forming a substantially larger amount of new subperiosteal bone than adult animals The same was observed in the experiments of Trueta and Cavadias (1955) with Küntscher nailing of rabbit radii Intensity and extent of the cortical necrosis could definitely be determined in the histological material after 2 weeks (fig 53) The cortical necrosis was to be regarded as the result of a single event (Willert and Puls 1972) and could be directly related to the trauma inflicted the destruction of the medullary blood vessels and the type of cement introduced

In *group 1* the enormous regenerative power of the medullary vascular system was confirmed after complete destruction of the medullary blood vessels by reaming of the medullary cavity and suction drainage of medullary contents (fig 38A fig 40) By virtue of a vent cut in the femur which prevented spread of the cortical ischaemia as a result of intracortical circulation block caused by fat embolism (Danckwardt Lillieström 1969 Danckwardt Lillieström et al 1970b) the cortical necrosis was confined to a narrow zone on the endosteal side (fig 53) From the

second postoperative week on, a new endosteal layer of bone was already deposited from a regenerated endosteum (fig 13, fig 50), in terms of thickness, this layer was no longer distinguishable from the normal growth remodelling in the control sections after 6 weeks (fig 18) and 7 weeks (fig 49B) After 3 months the necrotic tissue was found to have been almost completely replaced by vital bone (fig 24), and after 6 months restoration could be described as complete

No essential histological (figs 14, 19, 25) and (micro)angiographic differences (figs 38C, 41) between group 1 and *group 2* were demonstrable (fig 53) Apparently the residual monomer, gradually diffusing from the set material, had had no detrimental effect This was confirmed by the connective tissue membrane which developed around the Palacos rod from the 2nd week on The set-up of this experiment thus made it possible to corroborate the view of the authors quoted by Contzen et al (1967), Slooff (1970) and Charnley (1970) that polymerized acrylic cement which is not submitted to stress is a biocompatible material (cf chapter 1, page 25)

In *group 3*, necrosis of the inner one-half to two thirds of the cortex was observed 2 weeks after complete destruction of the medullary vascularization and additional introduction of the commercial cements Palacos and Sulfix 6 (fig 15) The extent of this necrosis, schematically represented in fig 53, can only have been caused by local side effects of acrylic cement – high polymerization temperature and cytotoxic monomer – if compared with the findings in group 1 No essential differences were histologically demonstrable between the commercial acrylic cements Palacos and Sulfix 6 applied in the two series (groups 3A and 3B)

Organization of this necrosis was very slow, and associated with the development of large [illegible]

[illegible] osteum was observed from which a very modest endosteal bone layer was deposited (figs 20, 49C, 49F, 49G) In comparable experiments carried out on dogs by Slooff (1970, 1971) and Lindwer (1972, 1975), *incipient* formation of a connective tissue membrane was already observed after 2 weeks, in our experiment this did not appear until later A first indication was observed after 7 weeks, and only after 6 months was a connective tissue membrane a constant finding Since the periosteum in dogs reacts by more extensive formation of new bone (Danckwardt Lilliestrom 1969, Slooff 1970, 1971), it is possible that this difference should also be ascribed to the animal species used

Animal experiments of the type reported by Rietz (1968) and Szyszkowitz (1971) in which artificial lesions of bone were repaired by intramedullary and interfragmental introduction of acrylic cement (Szyszkowitz 1971) or by intramedullary

prostheses anchored with cement (Rietz 1968) are in our opinion hardly conclusive in assessing the tissue compatibility or incompatibility of acrylic cement The disturbance of the intramedullary vascularization is so extensive (and so unfavourably influenced by the instability of the implants) that it seems at best possible to conclude that this is an unsuitable method of osteosynthesis and an unsuitable experimental set up for assessment of the tissue compatibility of acrylic cement

Restitutio ad integrum was not ultimately achieved *After 24 months* the entire inner half of the cortex proved to have been replaced by vital bone marrow This in turn was separated from the cement by a thick connective tissue membrane (fig 37) This finding was in agreement with the observations of Lindwer (1972, 1975), who introduced commercial acrylic cement into dog femurs after removing medullary contents In similar experiments on dogs, Slooff (1970, 1971) observed identical short term histological changes (maximum observation period 109 days) This very slow and incomplete repair of the tissue damage inflicted will have to be explained largely on the basis of markedly delayed regeneration of the medullary vessels (figs 42, 45) Revascularization appears to be greatly impeded when a solid mass of cement blocks completely the medullary blood flow, unlike the medullary revascularization which can occur in the flutes of a tight-fitting nail (Rhinelander 1972, 1973) Corroborative evidence is supplied by the observations of Brookes and Gallannaugh (1975), who in a haemodynamic study following implantation of acrylic cement in rat tibiae established hypovascularity of the bone after as many as 16 weeks Unlike Lindwer, who from his experiments derived far-reaching conclusions and recommendations for the clinical use of acrylic cement, we would only conclude that acrylic cement setting in situ can be described as a biologically non-inert substance which can cause permanent structural changes in bone tissue

The most severe tissue damage was found *in group 4* After interruption of the medullary vascularization and introduction of an acrylic „cement" with an abundance of monomer (about 30 volume per cent), virtually complete necrosis of the cortex was observed after 2 weeks (fig 53) This necrosis was not only very extensive but also very intensive (fig 16) Histological and autoradiographic (fig 51) examination disclosed enormous periosteal activity, the cortical diameter even being doubled at some sites (fig 49D) The regeneration of the cortex was even slower than that in group 3 (figs 21, 27) After 7 weeks new endosteal bone had still not been formed (fig 49D) Only after 3 months (fig 27) was this histologically demonstrable, and the autoradiogram after 4 months showed only scanty endosteal activity After 6 months there was as yet no histological evidence that the process of cortical regeneration was completed (fig 32) As in group 3, the incomplete and delayed revascularization of the medullary cavity must have been an important factor in this respect (fig 43) Since the „cement" did not polymerize and therefore produced no heat,

the tissue damage (in so far as it was not caused by the interruption of the medullary vascularization) can be ascribed to the cytotoxic monomer It is quite conceivable that very intensive necrosis could result from invasion of the bone by monomer leaking through the cortical canals

The effect of an overdose of monomer becomes even more apparent when we compare the above findings with those in *group 5*, in which the high temperature factor was likewise excluded After complete destruction of the medullary vascularization (fig 38B) and additional intramedullary application of a modified acrylic cement, observations after 2 weeks showed a slightly more extensive cortical necrosis than that in groups 1 and 2 This is schematically represented in fig 53

Regeneration of the necrotic part of the cortex (fig 17) was significantly more rapid than that in groups 3 and 4 (figs 22, 28) The histological findings closely resembled those obtained in the first two groups Particularly characteristic in this respect were the fluorescence microscopic features of the endosteal cortex apposition after 7 weeks (fig 49E) New, well vascularized bone and bone marrow tissue proved to grow into the pores of the gel-cement from the 6th week onwards (figs 23, 49E) The longer the observation period, the heavier was the growth of bone into the cement pores (figs 29, 30, 35, 52) This was a constant finding

There was even almost complete restoration of the cortex after 6 months (fig 33), so that the situation after application of the modified acrylic cement could be described as one of transient necrosis with maintenance of the integrity of the cortical structure Undoubtedly, this favourable course must have been made possible by the rapid, intensive regeneration of medullary vessels which was observed after as few as 2 weeks in histological sections as well as in micro angiograms (figs 44, 46 47) This early and vigorous revascularization of the medullary system contrasted sharply with the slow and sparse restoration of the medullary circulation in groups 3 and 4

Applying the „subtraction" method mentioned in chapter 3 (page 48) to groups 3 and 5, we are left with the high polymerization temperature of the commercial acrylic cement, since the *monomer concentration in* Palacos Sulfix 6 and modified Sulfix 6 remained the same The significant difference in extent of cortical necrosis between the two groups will therefore have to be explained *on the basis* of the temperature effect of acrylic cement setting in situ The principal local untoward side effect of acrylic cement is therefore the high polymerization temperature Of course this does not exclude any possible local side effect of the *cytotoxic* monomer The disastrous effect of an overdose of monomer was clearly demonstrated in group 4 Apparently small amounts of monomer produce no tissue damage (group 2) In order to quantify the monomer effect, a comparison could be made between group 5 and group 1, the difference being described as monomer effect In this comparison, however, the

effect of the filling of the medullary cavity is introduced as an unknown factor The results of this experiment, therefore, warrant no exact conclusion as to the quantitative cytotoxic effect of the monomer escaping during polymerization It seems justifiable, nevertheless, to describe this effect as minimal when compared with the effect of the high polymerization temperature

4 9 2 Discussion of the techniques used

The micro-angiographic technique used made it possible to fill the vessels on the afferent side of the circulation in so far as they were functional at the time of Micropaque perfusion The technique failed to visualize a sufficient vascular area to warrant any conclusion about the direction of flow Rhinelander's concept (fig 3) of the circulation in diaphyseal cortical bone could therefore be neither confirmed nor refuted Essential differences between Rhinelander's technique (Rhinelander et al 1962) and ours were to be found in the perfusion technique, thickness and calcium content of the section and the use of a stereo-viewer (Rhinelander uses decalcified sections, 1 mm thick, which are radiographed from two different angles and viewed with a stereo-viewer) Because our sections were used for fluorescence microscopy after microradiography, they had to be 100 micra thick and could not be decalcified

Some support for Rhinelander's theory could be found in the fluorescence-microscopic findings in groups 3 and 4 It was evident that unmistakably more new osteons had been formed in the region of the lineae asperae* than elsewhere in the cortex (figs 49C, D, F, G) This might be explained by the fact that the outer one-third of the cortex is supplied by periosteal arterioles in areas of heavy fascial attachment Our micro-angiographic technique was insufficient to confirm this

The fluorescence technique used was satisfactory The new fluorochromes calcein blue and green, xylenol orange and Alizarin complexon produced distinct differences in colour and were virtually free from fading The calcein green dose used proved to be too large because this fluorochrome superseded the other colours, this posed some problems in photography The colour intensity of Alizarin Red S was not very satisfactory

Little new information was obtained from the macro autoradiograms

---

* Unlike the dog femur the rabbit femur has two lineae asperae The postero-lateral line extends from the third trochanter to the lateral supracondylar tuberosity the posteromedial line extends from the lesser trochanter to the medial supra condylar tuberosity Barone et al (1973) referred to a labium laterale and a labium mediale with the facies aspera in between

Micro-autoradiography would be preferable for further investigations Finally, the dissolution of the acrylic cement during the processing of the material was experienced as a disadvantage

4 10 *Conclusions*

1 Complete interruption of the medullary circulation by reaming and suction of the rabbit femur provokes a number of typical reactions in

2 Commercial acrylic cement setting in situ is a biologically non inert material which causes local tissue damage

3 The principle side effect responsible for this damage is the high polymerization temperature The thermic tissue damage caused by acrylic cement far exceeds the necrosis which results from ischaemia

4 An overdose of monomer (about 30 volume per cent) causes severe tissue damage Minute amounts of monomer diffusing from set acrylic cement (so-called residual monomer) are not detrimental The monomer which escapes during polymerization after implantation of acrylic cement in a dough like state may also contribute slightly to the resulting tissue damage

5 A new modified acrylic cement which eliminates the high polymerization temperature is found to be much more readily tolerated by the tissues than the commercial acrylic cements Palacos and Sulfix-6 These do not differ essentially in terms of tissue damage caused In the porous modified cement bone is observed to grow into the pores from the 6th postoperative week on This in growth of bone runs parallel to the period of observation

effect of the filling of the medullary cavity is introduced as an unknown factor The results of this experiment, therefore, warrant no exact conclusion as to the quantitative cytotoxic effect of the monomer escaping during polymerization It seems justifiable, nevertheless, to describe this *effect as minimal when compared with the effect of the high* polymerization temperature

4 9 2 Discussion of the techniques used

The micro angiographic technique used made it possible to fill the vessels on the afferent side of the circulation in so far as they were functional at the time of Micropaque perfusion The technique failed to visualize a sufficient vascular area to warrant any conclusion about the *direction of flow Rhinelander's concept (fig 3) of the circulation in* diaphyseal cortical bone could therefore be neither confirmed nor refuted Essential differences between Rhinelander's technique (Rhinelander et al 1962) and ours were to be found in the perfusion technique, thickness and calcium content of the section, and the use of a stereo-viewer (Rhinelander uses decalcified sections, 1 mm thick, which are radiographed from two different angles and viewed with a stereo-viewer) Because our *sections were used for fluorescence microscopy after* microradiography, they had to be 100 micra thick and could not be decalcified

Some support for Rhinelander's theory could be found in the fluorescence-microscopic findings in groups 3 and 4 It was evident that unmistakably more new osteons had been formed in the region of the lineae asperae* *than elsewhere in the cortex (figs 49C, D, F, G) This might* be explained by the fact that the outer one third of the cortex is supplied by periosteal arterioles in areas of heavy fascial attachment Our microangiographic technique was insufficient to confirm this

The fluorescence technique used was satisfactory The new fluorochromes calcein blue and green xylenol orange and *Alizarin complexon* produced distinct differences in colour and were virtually free from fading The calcein green dose used proved to be too large because this fluorochrome superseded the other colours, this posed some problems in photography The colour intensity of Alizarin Red S was not very satisfactory

Little new information was obtained from the macro autoradiograms

* Unlike the dog femur the rabbit femur has two lineae asperae The posterolateral line extends *from the third trochanter to the lateral supracondylar tuberosity* the posteromedial line extends from the lesser trochanter to the medial supracondylar tuberosity Barone et al (1973) referred to a labium laterale and a labium mediale with the *facies aspera in between*

direct correlation was demonstrated between the extent of cellular necrosis on the one hand, and exposure time and temperature on the other (Mathews and Hirsch 1972, Lundskog 1972) The hypothesis (pages 17, 18) that thermic necrosis would be less in the case of an intact blood circulation, was not confirmed Both Matthews and Hirsch (1972) and Lundskog (1972) considered it unlikely that the cooling effect of the cortical circulation could be important in this respect The high temperature to which the bone is exposed after implantation of acrylic cement, persists several minutes (fig 1, 5) Our own conclusion therefore is that, while a temperature of 56° C may be the critical limit for denaturation of certain proteins (Lehnartz 1959) the limit for cellular bone necrosis caused by acrylic cement is significantly lower

The imperfections of traditional implant materials have prompted further investigation Granted that the ultimate purpose is the achievement of a biological fixation between implant and bone, several porous materials have recently been developed, which combine adequate tissue compatibility with sufficient material strength Investigators of biomaterials have had to do an enormous amount of work before the most suitable materials could be selected and the suitable porosity percentage and minimal pore size, shape and interconnection permitting in growth of hard tissues could be determined The substantial body of information available on these implant materials has been recently compiled by such authors as Homsy et al (1972) Hulbert et al (1973) and Smith (1974) Bone in growth has been demonstrated in porous ceramics, carbons, metals and polymers With the aid of certain types of glass (bioglass) an intensive chemical binding with bone can be achieved (Hench and Paschall 1974)

However, these porous materials do not ensure immediate fixation in bone, as does acrylic cement For orthopaedic applications, prostheses made of porous material or given a porous coating would have to be exactly made to measure in advance to ensure intimate contact with the implant bed Next, movements between bone and implant would have to be prevented for a number of months, or a temporary fixation would have to be used until sufficient bone in growth had taken place For temporary fixation the use of biostable or partly biodegradable bone cements has been suggested (Griss et al 1973)

The modified acrylic cement used in our experiments comes close to this ideal The aqueous gel phase is biodegradable Good tissue acceptance is achieved by drastic reduction of the high temperature effect

In two other [illegible]

[illegible] oxide (Smith 1968) [illegible] is a cement based on polymethacrylate with tributylborane as special catalyst system Both materials are described as capable of chemical binding to

CHAPTER 5

CLOSING REMARKS

Many factors contribute to the success of an implant arthroplasty The best results are obtained by careful determination of indications, an optimal surgical technique, adequate cementing, the use of a prosthesis of high mechanical properties, prevention of infection and adequate post-operative guidance of the patient The initial fixation of the prosthesis has been greatly simplified by the introduction of acrylic cement The question is how long the good result lasts In the long run a number of new problems present themselves Late loosening of the prosthesis and inexplicable complaints of pain necessitate more often revision operations The principal problem of implant arthroplasty continues to be the bone-implant interface It is in this interface that biologically and biomechanically undesirable tissue changes occur in reaction to acrylic cement (Willert and Puls 1972, Walker 1973, Muller 1974a, 1974b, Hirsch 1974)

This study has clearly demonstrated that the high polymerization temperature, even with the very small quantities used in this study, is the principal untoward side effect of acrylic cement It has been explained in chapter 1 (section 1 2 3) that there is no agreement how much the temperature rises in the interface between bone and acrylic cement In the German literature a temperature of 56° C is accepted as critical limit

Burns caused by acrylic cement have been described in a few case reports (Jefferis 1971) The remnants of the acrylic cement used in a total hip arthroplasty burned through the surgical drapes and caused lesions of the patient's abdominal skin The threshold value for thermic necrosis of epithelial cells is 52-55° C at an exposure time of 30 seconds (Kuhl et al 1954, Moritz and Henriques 1947, quoted by Lundskog 1972)

The superbly documented experiments on the immediate effect of various temperatures and exposure times on vital bone tissue, performed by Lundskog (1972) showed conclusively that the osteocytes have about the same threshold value for thermic necrosis as epithelial cells in cutaneous tissue At an exposure time of 30 seconds, the threshold value for osteocytic necrosis was found to be 50° C (Lundskog 1972) Moreover, a

Discussing the physical properties of commercial acrylic cement, Lautenschlager et al. philosophized in 1974: „Perhaps someday superior cements will be developed. Cements where such things as exothermic temperature rise and residual monomer from incomplete polymerization are not potential problems. Perhaps someday cements of a controlled surface porosity for tissue in growth to aid fixation, cements with mechanical properties matched to bone and prosthesis alike to forever forbid loosening, and cements with additives which will produce proper radiopacity and contribute to the prevention of infection will become available."

Some of the ideal properties enumerated in this statement seem to have been incorporated in this material. The future will show whether it is clinically applicable.

organic components of hard tissues For orthopaedic applications these cements are still in the experimental stage (Peters et al 1972, Iida et al 1974) but they should be mentioned here as possible alternatives for acrylic cement

The decrease in temperature of the modified cement results on the one hand from the good heat-conducting capacity of the aqueous phase, and on the other hand from a relative reduction of the amount of monomer by admixture of the gel (de Wijn 1975) A possible disadvantage of the lower maximum temperature lies in a probably less complete polymerization of the mixture, in view of which some loss of mechanical properties is to be expected (Puhl and Schulitz 1971) However, an attempt to alter the maximum temperature can be made only at the cost of some decrease in mechanical strength An advantage of the lower temperature is that less shrinkage occurs as a result of lower thermic cooling The smaller percentage of acrylic cement also contributes to this In view of the hydrophilic properties of the gel, the cement can in fact be expected to expand

Other interesting features are that the duration of the curing time does not differ from that of the commercial product (fig 5), and that substances such as antibiotics, cytostatics, etc can be dissolved in the gel (de Wijn 1975)

At 35 per cent porosity, a pore diameter of 50-150 micra and good pore interconnection – all readily reproducible characteristics – the material is fairly strong, when compared with commercial cement its compressive strength is about 50 per cent (de Wijn 1975) In this loss of mechanical strength it does not differ from other porous materials However, in-growth of hard tissues (figs 23, 29, 30, 35, 46, 47, 49E, 52) can considerably reinforce the material in situ and (more important) effect optimal fixation between bone and implant The mechanisms of bone in-growth in porous materials are still unexplained (Hulbert et al 1973) Strong arguments have been presented in support of the suggestion that electrical phenomena are directly involved in osteogenesis (Bassett 1971) Applying the three criteria for bone induction formulated by Chalmers et al (1975), it could be postulated that 1) the porous polymer is the *inducing stimulus*, it works as a dipole, producing free surface energy (Bassett 1971, 1975), 2) young bone marrow cells act as *osteogenic precursor cells*, 3) the CMC gel creates a *favourable environment for osteogenesis*

Further research with this new biocompatible material may lead to improvements It is important to establish whether the modified acrylic cement is sufficiently strong for temporary fixation of a prosthesis, and whether under stress (Bassett 1971, Hulbert et al 1974) bone in growth can be accelerated and increased to such an extent that biological fixation between bone and implant results Another possible application might be that of filling substance for cancellous or non-weightbearing bone defects

sults After discussion of the results and of the techniques used, the chapter closes with a number of conclusions

The results obtained in the experiments provide a definite answer to the question posed in the problem statement After implantation, the high polymerization temperature of the acrylic cement causes changes in bone tissue which in intensity and extent far exceed the ischaemic cortical necrosis due to the surgical preparation of the medullary cavity (reaming and suction) Whether the monomer escaping after implantation of acrylic cement contributes to the tissue changes is not certain If it does, then its contribution is certainly a small one

A modified porous acrylic cement (Sulfix 6 with CMC gel), which differs from commercial acrylic cements in that the high polymerization temperature as tissue-damaging factor has been eliminated, shows unmistakably superior tissue tolerance Moreover, shortly after its implantation growth of well vascularized bone into the pores of the un stressed cement is observed, a growth which increases with the period of observation

Chapter 5 discusses, among other things, the potential clinical application of this new porous acrylic cement

SUMMARY

The three factors generally regarded as causes of the tissue changes in bone after acrylic cement implantation are the high polymerization temperature of acrylic cement, the cytotoxicity of the monomer and the interruption of the osseous vascularization by the surgical preparations for the implantation. The principal objective of this experimental study was to establish which of these three factors is the most important. The rabbit femur was chosen as experimental model.

Chapter 1 presents recent views on the physical, chemical, pharmacological and biological properties of acrylic cement when applied as filler substance for the fixation of prostheses in bone. The tissue changes which occur in the new joint capsule and the bony implant bed after total hip replacement are described.

Chapter 2 discusses the topographical anatomy of the vascularization of the rabbit femur and the functional anatomy of the cortical vascularization of the diaphysis of long bones in general. Intramedullary interventions which result in complete block of the medullary circulation, disturb the physiological pattern of vascularization. The changes in the diaphyseal cortical circulation and the reactions provoked by ischaemia in medullary cavity, cortex and periosteum are discussed. In this context great importance is attached to the increased intramedullary pressure and the intracortical bone marrow embolism related to it.

Chapter 3 explains the argumentation underlying the experiments. Three types of cement are used: 1) commercial acrylic cement, 2) a catalyst-free „acrylic cement" in which no polymerization reaction (and therefore no heat generation) occurs, an excess of monomer being left, 3) a modified porous acrylic cement in which the high temperature effect has been drastically reduced, the monomer content remaining unchanged. The operative technique used is described and discussed. The grouping of the test animals in accordance with the cement type implanted is explained. The chapter closes with a discussion of the laboratory techniques used.

Chapter 4 presents an analysis of the results obtained, with emphasis on a comparison of the tissue changes observed in the different groups. The findings obtained in the histological material are supplemented with (micro)angiographic, fluorescence microscopic and autoradiographic re-
